Ethnolinguistic Favoritism in African Politics

Andrew Dickens[†]

Final Version

African political leaders have a tendency to favor members of their own ethnic group. Yet for all other ethnic groups in a country, it is unclear whether having a similar ethnicity to the leader is beneficial. To shed light on this issue, I use a continuous measure of linguistic similarity to quantify the ethnic similarity of a leader to all ethnic groups in a country. Combined with panel data on 163 ethnic groups partitioned across 35 sub-Saharan countries, I use within-group time variation in similarity that results from a partitioned group's concurrent exposure to multiple national leaders. Findings show that ethnic favoritism is more widespread than previously believed: in addition to evidence of coethnic favoritism, I document evidence of non-coethnic favoritism that typically goes undetected in the absence of a continuous measure of similarity. I also find that patronage tends to be targeted toward ethnic regions rather than individuals of a particular ethnic group. I relate these results to the literature on coalition building, and provide evidence that ethnicity is one of the guiding principles behind high-level government appointments.

1 Introduction

Understanding why global poverty is so concentrated in Africa remains one of the most crucial areas of inquiry in the social sciences. One long-standing explanation is that Africa's high level of ethnic diversity is a major source of its underdevelopment and political instability (Easterly and Levine, 1997; Collier and Gunning, 1999; Posner, 2004; Alesina and La Ferrara, 2005; Ashraf and Galor, 2013, among others). Yet recent evidence documents that the source of underdevelopment is not ethnic diversity per se, but rather Africa's high degree of inequality between ethnic groups (Alesina et al., 2016). This suggests that ethnic diversity is only an impediment to economic development when some ethnicities prosper at the expense of others.

Ethnic inequality not only contributes to the under-provision of the overall level of public resources (Baldwin and Huber, 2010), but it provokes discriminatory policies that advantage some groups over others (Alesina et al., 2016). Discriminatory policies of this type are a form of ethnic favoritism, which has been the subject of a few influential papers that document evidence of public resource distribution across ethnic lines in Africa (Franck and Rainer, 2012; Burgess et al., 2015; Kramon and Posner, 2016). The provision of resources on the basis of ethnicity – rather than on a need or marginal value basis – suggests that some ethnic groups are being systematically favored over others. Hence, a better understanding of how ethnic patronage is distributed and to whom is important because it sheds light on the extent to which favoritism occurs and how some ethnic groups benefit at the expense of others.

In this paper I revisit the study of ethnic favoritism with three contributions. My first contribution is a measure of linguistic similarity that quantifies the relative similarity of all ethnic groups to the national leader in each country, not just groups that share an ethnicity with the leader (i.e., coethnics). Because linguistic similarity is measured on the unit interval it encompasses the commonly used coethnic dummy variable, while extending measurement to all non-coethnic groups.[1] The continuity of this measure implies that *any* change in the ethnic identity of a leader is associated with *some* change in the similarity of *all* groups in a country, an important source of variation that is not observable using a coethnic dummy variable. The additional variation this continuity provides is quite substantial given that the majority of Africans are never coethnic to their leader.[2] I also use the continuity of similarity to show that favoritism exists among groups that are not coethnic to the leader,

---

[1]People identify as coethnics because they share a common ancestry and language, hold similar cultural beliefs and pursue related economic activities (Batibo, 2005). In this way, linguistic similarity is a good measure of ethnic proximity because it is the most visible marker of ethnic identity.

[2]Using population data from the Ethnologue (16th edition), I calculate that only 34 percent of the median sub-Saharan country's population was *ever* coethnic to their leader between 1992 and 2013.

a new finding that is a contribution in itself. This speaks to why a continuous measure of ethnic similarity is important: ethnic favoritism is under-reported when using a coethnic dummy variable because non-coethnic favoritism goes undetected.

My second contribution relates to the evidence that ethnic favoritism is widespread throughout sub-Saharan Africa. I use the systematic partitioning of African ethnic groups across political borders to expand the scope of evidence relative to previous studies. In particular, I exploit the fact that the same ethnic group is split between neighboring countries and exposed to a different ethnic leader on each side of the border. As different ethnic leaders come and go from power, the relative similarity of a partitioned group varies over time. I use this variation in a triple difference set-up and document evidence of ethnic favoritism in two empirical settings: a panel of 163 ethnic groups split across 35 countries, and a repeated cross-section of individuals living in 20 groups split across 13 countries.

For my third contribution I disentangle the relative importance of location-based favoritism from targeted transfers towards individuals. In either case, the ruler is trying to help individuals from similar groups. But in the absence of this distinction, it is not clear whether individuals from a similar group only benefit because of targeted transfers, or whether all individuals of an ethnic region benefit from location-based favoritism irrespective of their own ethnic identity. To better understand how patronage is distributed, I use variation among survey respondents who identify with an ethnicity that is different from the ethnic region in which they live.[3] I find that patronage is distributed according to the ethnic identity of a region rather than as a targeted transfer towards individuals of a particular ethnic group.

Throughout this empirical analysis I rely on the fact that the location of African borders are quasi-random (Englebert et al., 2002; Michalopoulos and Papaioannou, 2014, 2016). The historical formation of Africa's borders began with the Berlin Conference of 1884-1885, where European powers divided up Africa with little regard for the spatial distribution of ethnic homelands (Herbst, 2000). This disregard led to the arbitrary formation of national borders, which "did not reflect reality but helped create it" (Wesseling, 1996, p.364). One such reality was the partitioning of approximately 200 ethnic groups throughout Africa.

In the context of this study, these quasi-random borders provide a source of exogenous within-group variation. The fact that the ethnolinguistic identity of a leader varies by country, and each partitioned group is split between two or more countries, a partitioned group's similarity to their leader varies because of the placement of political borders. Using partitioned ethnic groups as a source of variation in this way is methodologically similar to

---

[3]This is analogous to Nunn and Wantchekon (2011), who use a similar source of variation to separate internal norms of an individual from the external norms of an individual's environment.

Michalopoulos and Papaioannou (2014).

I use the Ethnologue's mapping of ethnolinguistic homelands across the world to locate these partitioned groups, which serve as my unit of observation for the benchmark analysis. Because no income data exists at this level of observation, I proxy an ethnic group's economic activity using annual satellite images of night light luminosity for the time period 1992-2013. I superimpose these yearly night light data onto the geographic location of sub-Saharan ethnic groups and I construct a panel of economic activity at the group level. Luminosity is frequently used as a measure of economic activity because of its strong empirical association with GDP per capita and other measures of living standards (Henderson et al., 2012; Michalopoulos and Papaioannou, 2013, 2014; Alsan, 2015; Alesina et al., 2016, among others). Hodler and Raschky (2014) first used luminosity in this way to study patterns of regional favoritism.

Consider, as an example, the Jola-Fonyi partitioned across Gambia and Senegal. In 1993, both the Gambian and Senegalese Jola-Fonyi bear little resemblance to their respective leaders. For several years little changed in Senegal as President Diouf's reign continued. On the contrary, much changed for the Gambian Jola-Fonyi when Yahya Jammeh, a young officer in the National Gambian Army, overthrew President Jawara in a 1994 military coup. Jammeh was born in Kanilai, a small village near the southern border of Gambia and home to the Jola-Fonyi. Jammeh took much pride in his birth region – a "place that gained prominence overnight in Gambia" (Mwakikagile, 2010, p. 56). Jammeh repeatedly "feathered his nest" to such an extent that the Jola-Fonyi region surrounding Kanilai is one of few rural areas in Gambia with "electricity, street lighting, paved roads and running water – not to mention its own zoo and game preserve, wrestling arena, bakery and luxury hotel with a swimming pool" (Wright, 2015, p. 219).

Figure 1 provides visual evidence of this phenomenon. The two panels represent the same subsection of the Jola-Fonyi at two points in time, with the border dividing Gambia to the north and Senegal to the south. While there is no visible night light activity on either side of the border in 1993, there is a significant increase in lights on the Gambian side only 5 years after Jammeh assumed power. On the contrary, Diouf's presidency continued throughout this entire period and there is no observable change in night light activity in Senegal just south of the border. This demonstrated change in Figure 1 is exactly the within-group variation that I use to estimate the effect of similarity. In this case, the Senegalese Jola-Fonyi are the counterfactual observation for the Gambian Jola-Fonyi, who are equally dissimilar in language to their incumbent leader in 1993, and the effect of similarity on night light activity is estimated off of the change in linguistic similarity following Jammeh's rise to power.

My benchmark results imply that a standard deviation increase in linguistic similarity

Figure 1: Change in Night Lights Intensity from 1993-1999
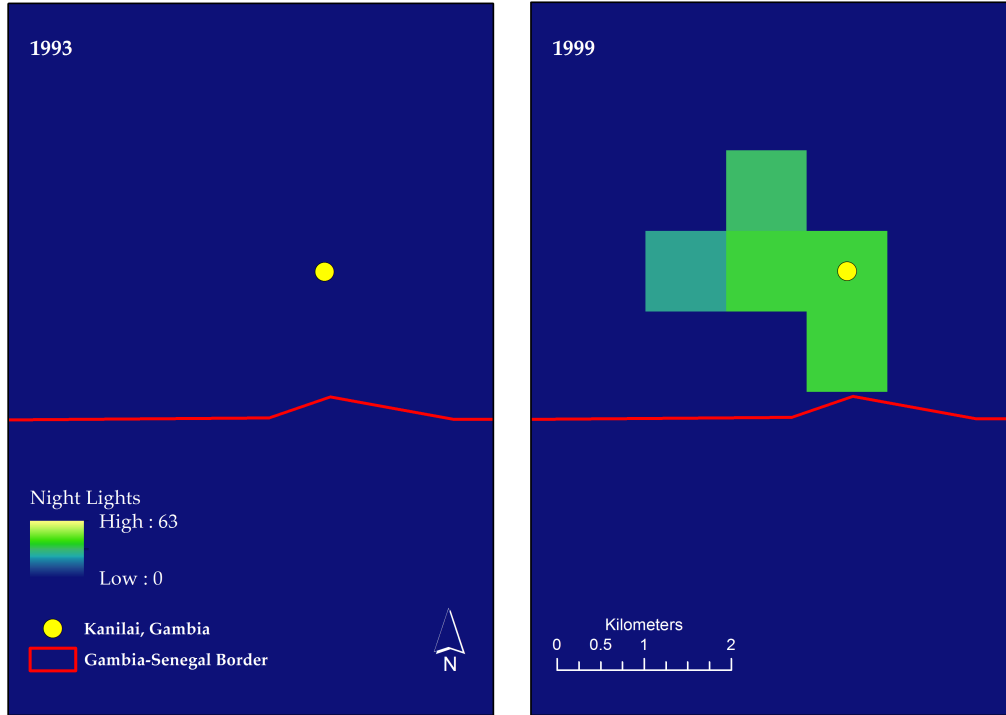

This figure documents the change in night light activity in the partitioned Jola-Fonyi region of Gambia (north of the border) and Senegal (south of the border) between 1993 and 1999. In 1994, Yahya Jammeh assumed power of Gambia and soon after started reallocating funds to the Jola-Fonyi. Within 5 years of presidency the Gambian Jola-Fonyi exhibit much greater economic activity in terms of night lights than the Senegalese Jola-Fonyi on the south side of the border, whom had no change in leadership during this period.

(23 percent) yields a 7 percent increase in luminosity and a 2 percent increase in group-level GDP per capita. I also use the continuity of linguistic similarity to document evidence of non-coethnic favoritism, where the mean non-coethnic effect is one quarter the coethnic premium. To the contrary I find no evidence of anticipatory effects in the data or evidence of migration in response to leadership changes. To be sure this result is not a consequence of my new measure of similarity I construct two alternative measures: a standard binary measure of coethnicity and a discrete similarity measure of the ratio of shared nodes on the Ethnologue language tree. While these alternative measures of similarity yield significant evidence of favoritism, my preferred lexicostatistical measure of similarity is more precisely estimated and the only measure to maintain significance in a series of horse race regressions.

I also test for a variety of mechanisms, but find no systematic evidence of the usual channels (e.g., democracy). However, I do find that the extent of favoritism is increasing in the years a leader has held office. This suggests that one determinant of favoritism is leadership tenure.

Next I turn to individual-level data from the Demographic and Health Survey (DHS). I use survey cluster coordinates to pinpoint the location of individual respondents on the Ethnologue map. Doing so allows me to construct a repeated cross-section of individuals living in partitioned ethnic groups across DHS survey waves. Narrowing the focus to these individuals allows me to exploit cross-border variation in an empirical setting that is similar to my main analysis. As an outcome I use an individual-level measure of access to public resources and ownership of assets. I corroborate my benchmark findings with these individual-level data, including evidence of non-coethnic favoritism. I also establish that patronage is distributed regionally and not as a targeted transfer towards individuals.

These findings speak to a sparse but growing body of evidence that ethnic favoritism is widespread throughout Africa. Franck and Rainer (2012) use a panel of ethnic groups in 18 countries to document evidence of favoritism throughout sub-Saharan Africa. What sets my paper apart from Franck and Rainer's (2012) is that I construct a panel of *partitioned* ethnic groups, so I have a minimum of two country-group observations for any partitioned group in a year. This feature of my data affords me ethnicity-year fixed effects. Because I can account for all observable and unobservable time-varying features of an ethnic group, I am able to rule out all endogeneity concerns associated with a group's history in that country, including the impact of pre-colonial group characteristics on contemporary development (Gennaioli and Rainer, 2007; Michalopoulos and Papaioannou, 2013; Fenske, 2013).

More commonly researchers focus on a single patronage good in a single country. Kramon and Posner (2016) find that Kenyans whom are coethnic to their leader attain higher levels of education, while Burgess et al. (2015) find that Kenyan districts associated with the leader's ethnicity receive two times the investment in roads during periods of autocracy. At an even finer level, Marx et al. (2017) document evidence of ethnic favoritism in housing markets within a large slum outside of Nairobi.

The rich micro-data these studies use provide clear evidence of ethnic favoritism and the channels through which patronage is distributed. Yet generalizing these results is difficult because of the highly localized analyses these studies employ. To this end, De Luca et al. (2015) document that ethnic favoritism is an axiom of politics on a global scale and not simply an African phenomenon. As this literature continues to grow, these localized studies coupled with the broader evidence of ethnic favoritism help to build consensus around ethnic favoritism in Africa.[4]

In the discussion section of this paper I provide evidence that leaders appoint similar

---

[4]Yet consensus on ethnic favoritism if Africa has not been reached. Francois et al. (2015) document that leaders only provide a small premium to their coethnics, and otherwise political power is proportional to group size in Africa. Kasara (2007) finds that leaders are more likely to extract taxes from their own ethnic group because they have a better understanding of internal markets in their homeland.

but not identical ethnic elites to high-level government positions for this purpose. In doing so, non-coethnic groups gain coethnic representation in government, where representatives speak on their behalf and channel resources to them (Arriola, 2009). This is in line with the idea that leaders bring elites from outside of their ethnic group into the governing coalition in an effort to sustain power in the face of political instability (Joseph, 1987; Francois et al., 2015). Although my focus is Africa, this deeper understanding of where favoritism is expected to take place has implications for distributive politics more broadly: it contributes to our knowledge of how targeted transfers can potentially magnify inequality between groups and thus is informative of a determining factor of comparative economic development.

The notion that ethnic favoritism drives discriminatory policies that disadvantage some groups at the expense of others also relates this research to the literature on ethnic inequality and conflict. Alesina et al. (2016) document that the negative correlation between ethnic inequality and economic development is a global phenomenon, though most pronounced in Africa. Income differences between a country's ethnic groups can also impact the political process: ethnic inequality mitigates public good provision (Baldwin and Huber, 2010), diminishes the quality of governance (Kyriacou, 2013), and provokes the "ethnification" of political parties (Huber and Suryanarayan, 2014). At the heart of this literature is the long-standing instrumentalist view that conflict over scarce resources drives ethnic competition in Africa (Bates, 1974). Even the perception of ethnic favoritism exacerbates already existing ethnic tensions (Bowles and Gintis, 2004), which itself can further incite ethnic conflict (Esteban and Ray, 2011; Esteban et al., 2012; Caselli and Coleman, 2013).

The rest of this paper is structured as follows. Section 2 describes the data and Section 3 outlines the identification strategy and empirical model. Section 4 reports the benchmark estimates and robustness checks. Section 5 disentangles the relative importance of location-based favoritism from individual-level favoritism, and in Section 6 I link the findings to the literature on ethnic favoritism and coalition building, and provide suggestive evidence that non-coethnic favoritism works through the appointment of elites from outside of the leader's ethnic group. Section 7 concludes.
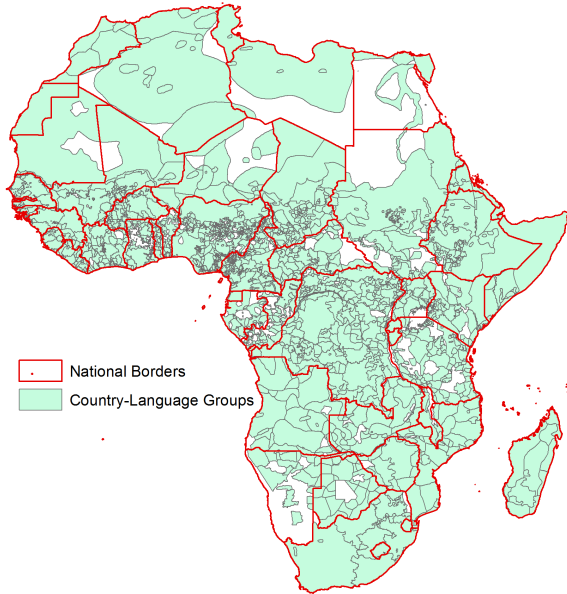

2 Data

2.1 Language Group Partitions

I construct language group partitions using the 2009 Ethnologue (16th edition) mapping of language groups from the World Language Mapping System (WLMS). These WLMS data depict the spatial distribution of linguistic homelands at the country-language group level

Figure 2: Language Groups   **Figure 3:** Language Partitions
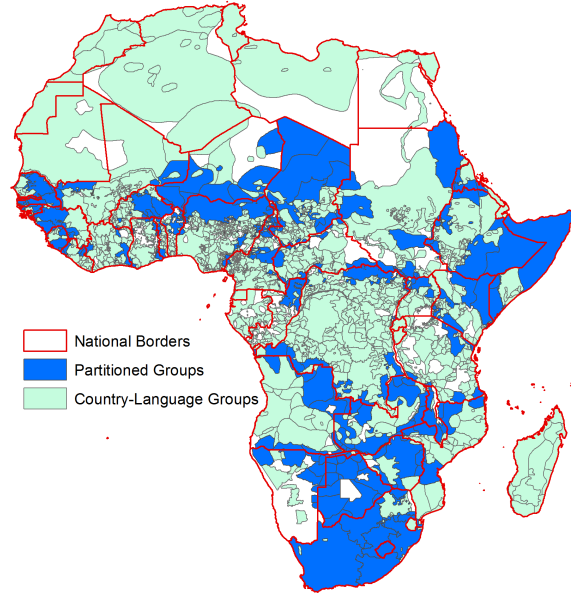

(Figure 2). I focus on continental sub-Saharan Africa.[5] In total there are 2,384 country-language group observations reflecting 1,961 unique language groups in 42 continental African countries.[6]

I define a partition as a set of contiguous country-language group polygons, where each polygon in a set is part of the same language group but separated by a national border. I use ArcGIS to identify these partitioned groups, excluding country-language groups with a reported Ethnologue population of zero. The result is 486 remaining country-language group observations, made up of 227 language groups partitioned across 37 African countries.

2.2   Satellite Imagery of Night Light Luminosity

Satellite imagery of night light luminosity come from the National Oceanic and Atmospheric Administration's (NOAA) National Geophysical Data Center. Many others have used these data because of two features: night lights data exhibit a strong empirical relationship with GDP per capita and other measures of living standards (Henderson et al., 2012), and because these data are available at a spatial resolution of 30-arc seconds (approximately 1 square kilometre).[7] The fine resolution of these lights data facilitates a proxy measure of GDP per

---

[5]I use the United Nations classification of sub-Saharan countries. However, I include Sudan in the analysis because it is geographically part of sub-Saharan Africa and contains a number groups partitioned between Sudan and sub-Saharan countries.

[6]Because Western Sahara is a disputed territory I exclude it from this border analysis.

[7]Hodler and Raschky (2014) also show there is a strong empirical relationship between these night lights data and GDP at the subnational administrative region. Michalopoulos and Papaioannou (2014) further

capita at any desired level of spatial aggregation. Because I require a measure of economic activity at the country-language group level – a level of aggregation where no official data on economic output exists – the availability of these data is indispensable to this study.

The yearly composite of night light luminosity is constructed by NOAA using daily images taken from U.S. Department of Defense weather satellites that circle the earth 14 times a day. These satellites observe every location on earth every night sometime between 20:30 and 22:00. Before distributing these data publicly, NOAA scientists remove observations contaminated by strong sources of natural light, e.g., the summer months when the sun sets late, light activity related to the northern and southern lights, forest fires, etc. All daily images that pass this screening process are then averaged for the entire year producing a satellite-year dataset for the time period 1992 to 2013. Light intensity receives a value of 0 to 63 at a resolution of 30-arc seconds. The result is a measure of night light intensity that only reflects human (economic) activity.[8]

Using these data I construct a panel of average luminosity for each country-language group partition. I use the Africa Albers Equal Area Conic projection to minimize distortion across the area dimension before calculating the average light luminosity of each country-language group polygon in each year.[9] I follow Michalopoulos and Papaioannou (2013, 2014) and Hodler and Raschky (2014) in adding 0.01 to the log transformation of the lights data because roughly 40 percent of these data have a value of zero in the benchmark sample. Doing so helps correct for the non-normal nature of the data and preserves sample size, and allows for a (near) semi-elasticity interpretation of the benchmark empirical model.

2.3   Linguistic Similarity

My independent variable of interest is a measure of linguistic similarity between each partitioned group and the ethnolinguistic identity of a country's leader. The preferred measure is a lexicostatistical measure of linguistic similarity. As a percentage estimate of a language pair's cognate words (i.e., words that share a common linguistic origin), lexicostatistical similarity approximates the phonological similarity between two languages. Because the extent of this similarity is a function of time since two languages split from a common ancestral group, the lexicostatistical similarity of a group to their leader captures that group's ancestral relatedness to their leader (i.e., ethnic similarity).

---

validate the use of night lights in Africa as a proxy measure of development with evidence that light intensity correlates strongly with individual-level data on electrification, presence of sewage systems, access to piped water and education.

[8]Henderson et al. (2012, p. 998) provide a thorough introduction to the NOAA night lights data.

[9]In some years data is available for two separate satellites, and in all such cases the correlation between the two is greater than 99 percent in my sample. To remove choice on the matter I use an average of both.

I use a computerized approach to estimating lexicostatistical similarity that was developed by the Automatic Similarity Judgement Program (ASJP).[10] The ASJP Database (Version 16) consists of 4401 language lists, where each list contains the same 40 implied meanings (i.e., words) for comparison across languages. The ASJP research team has transcribed these lists into a standardized orthography called ASJPcode, a phonetic ASCII alphabet consisting of 34 consonants and 7 vowels. A standardized alphabet restricts variation across languages to phonological differences. Meanings are then transcribed according to pronunciation before language differences are estimated.[11]

For each language pair of interest I run the Levenshtein distance algorithm on the respective language lists, which calculates the minimum number of edits necessary to translate the spelling of each word from one language to another. To correct for the fact that longer words will demand more edits, each distance is divided by the length of the translated word. This normalization yields a percentage estimate of dissimilarity, which is measured across the unit interval. The average distance of a language pair is calculated by averaging across the distance estimates of all 40 words. By this procedure I estimate the linguistic distance of a language pair vis-à-vis the vocabulary dimension.

A second normalization procedure adjusts for the accidental similarity of two languages (Wichmann et al., 2010). This normalization accounts for similar ordering and frequency of characters that are the result of chance and independent of a word's meaning. Finally, I define the lexicostatistical similarity of a language pair as one minus this normalized distance.

I also construct two alternative measures of similarity. The first is a cladistic measure of similarity, which captures the number of shared branching points between any two nodes on a language tree. Cladistic similarity was introduced to economists by Fearon and Laitin (1999), popularized by Fearon (2003) and has been used elsewhere.[12] The idea behind the cladistic approach is that two languages with a large number of shared nodes – and thus a recent splitting from a common ancestor – will be similar in terms of language because of their common ancestry. The data most commonly used is Fearon's (2003) cladistic measure of linguistic similarity, constructed using the Ethnologue's phylogenetic language tree. The second measure is a binary measure of coethnicity that is equal to one when a leader's

---

[10]This lexicostatistical measure has been used to study factor flows in international trade (Isphording and Otten, 2013), job satisfaction of linguistically distinct migrants (Bloemen, 2013), language acquisition of migrants (Isphording and Otten, 2014), and the role of language in the flow of ideas (Dickens, 2016). The only other lexicostatistical data available for a large number of languages is from Dyen et al. (1992), which is restricted to Indo-European languages only – none of which are native to Africa. See Ginsburgh and Weber (2016) for a survey of these measures and more.

[11]For example, the French word for *you* is *vous*, and is encoded as *vu* to reflect its pronunciation.

[12]For example, Guiso et al. (2009); Spolaore and Wacziarg (2009); Desmet et al. (2012); Esteban et al. (2012) and Gomes (2014) all use a cladistic approach, among others.

Figure 4: Lexicostatistical Similarities Among Sibling Language Pairs
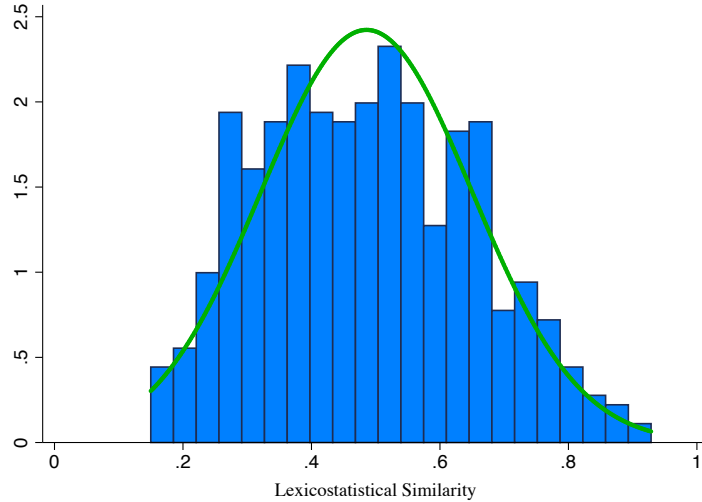

This figure establishes the additional variation introduced by a lexicostatistical measure of linguistic similarity that is not observable with a cladistic measure of similarity. The histogram plots the estimates of lexicostatistical similarity among sibling language pairs for all of Africa ($n = 1,241$). Sibling language pairs are those that share a parent language on the Ethnologue language tree, which by definition implies that among sibling language pairs there is no observable variation in cladistic similarity.

ethnolinguistic identity is the same as a partitioned language group.[13] Appendix A reports summary statistics for all variables and Appendix B provides a formal definition of all three measures of linguistic similarity.

Unlike the coethnic dummy variable typically used to study ethnic favoritism, the lexicostatistical and cladistic approach provide observable variation in similarity for non-coethnic groups. However, the main advantage of the lexicostatistical approach is that it measures similarity in a more continuous way than the cladistic approach. Because the lexicostatistical method explicitly identifies the phonological differences of a language pair, there is far more observable variation in a measure of lexicostatistical similarity than cladistic similarity. The cladistic approach is a coarse measure of similarity because data dispersion is limited to fifteen unique values, the maximum number of family classifications in the Ethnologue language tree.

To illustrate this point, consider language pairs that share a common parent language on the Ethnologue language tree. Let these language pairs be known as siblings. All sibling pairs share the maximum number of tree nodes, and have no differences in cladistic similarity between them, but they do exhibit substantial variation in lexicostatistical similarity. Figure

---

[13]I use the term coethnicity to be consistent with the literature, but a more precise name would be coethnolinguists since, by definition, my measure of coethnicity implies zero linguistic distance between a group and their leader.

4 plots the distribution of lexicostatistical similarities among all African sibling language pairs. This figure highlights the sizeable dispersion in lexicostatistical similarities even among sibling language pairs.

Assignment of a Leader's Ethnolinguistic Identity

Before measuring the similarity of a partitioned group to their leader, it is necessary to assign an ethnolinguistic identity to each leader. There are 106 leaders in my sample of 35 countries between 1992-2013. The challenge of mapping ethnicity to language is that, in some instances, a single ethnic group speaks many languages. Because African language groups are often resident of well-defined territories (Lewis, 2009), an ethnolinguistic identity is typically attached to a person's birthplace (Batibo, 2005). As a first step towards assignment I locate the birthplace of a leader and collect latitude and longitude coordinates for each birthplace from www.latlong.net. I project these coordinates onto the Ethnologue map of Africa to back out the language group associated with each leader's birthplace.[14] I exclude leaders born abroad (4 leaders) since their ethnolinguistic group is not home to the country they govern.[15] Second, I identify a leader's ethnic identity using data from Dreher et al. (2015) and Francois et al. (2015), and in the few instances where neither source reports the ethnicity of a leader I fill in the gap using a country's Historical Dictionary. Finally, I take the following steps to assign a leader's ethnolinguistic identity using these data:

Step 1: I compare the birthplace linguistic identity with the ethnic identity for each of the 102 leaders. In 56.9 percent of the sample the name of the birth language and ethnic identity are equivalent (58 leaders). For these leaders the assignment is unambiguous.

Step 2: For the remaining sample of unmatched leaders, I check if the birthplace language is a language spoken by the leader's ethnic group. In 12.7 percent of the sample this is true (13 leaders); I assign the birthplace language as the leader's ethnolinguistic identity.

Step 3: For the remaining 30.4 percent of unmatched leaders (31 leaders), the birthplace identity does not correspond to their ethnic identity. This is especially true for leaders born in a major city. For these leaders I drop the birthplace identity and map the ethnicity of a leader to a single language using the three-step assignment rule outlined in Appendix C.

---

[14]Because most leaders enter/exit office mid-year, I assign the incumbent leader as whomever is in power on December 31st of the transition year. Hence, by assumption I drop any leader who exited office the same year she entered office because she was neither in power the previous year or December 31st of the transition year.

[15]These leaders include Ian Khama (Botswana), Francois Bozize Yangouvonda (Central African Republic), Nicephore Soglo (Benin), and Rupiah Banda (Zambia).

Linguistic Similarity of Leaders and Language Groups

Because the computerized lexicostatistical method requires a word list for each language of interest, I am limited to working with languages that have lists made available by the ASJP research team. Of the 227 language groups in the full set of partitions I match 163 in the benchmark regression (72 percent), failing the rest either because the leader's birth language list is unavailable or the partition language list is unavailable. I address the possibility of sample selection bias in Table D4 in the Appendix. The result is an (unbalanced) panel of lexicostatistical similarity between partitioned language groups and their national leader for the years 1992-2013. Figure 3 colour codes these groups.[16]

2.4   DHS Individual-Level Data

I also collect data from the Demographic and Health Surveys (DHS) for 13 countries. For each country I pool both the male and female samples for each wave, and when separately provided, I merge the wealth index dataset for that year. To replicate the same variation I use in my benchmark estimates, I choose DHS countries and survey waves as follows:

(1) I identify all DHS country-waves that include latitude and longitude coordinates for each survey cluster as well as information on a respondent's home language and/or ethnic identity.

(2) I identify all language groups that are partitioned across contiguous country pairs in the DHS database that also possess the necessary information noted in (1).

(3) For each partitioned language group identified in (2) I keep those that possess at least 2 consecutive surveys from the same set of DHS waves.

Next I project the latitude and longitude coordinates for each survey cluster onto the Ethnologue language map and back out the language group associated with that location.[17] I assign this language as the locational language for that cluster and construct a measure of locational similarity as the lexicostatistical similarity of that region to the incumbent leader.

To measure individual similarity I use data on the language a respondent speaks at home, and when not available data on their ethnicity. I describe the mapping between ethnicity and language in detail in Appendix C. I construct a measure of individual similarity as the lexicostatistical similarity between the home language of an individual and the ethno-linguistic identity of their national leader. To be consistent with my benchmark model, I

---

[16]Appendix A reports summary statistics for all variables, and a complete list of countries and language groups included in the analysis.

[17]In instances of overlapping language groups, I assign the largest group in terms of population

Figure 5: DHS Clusters Across Waves in the Kuranko Language Group Partition
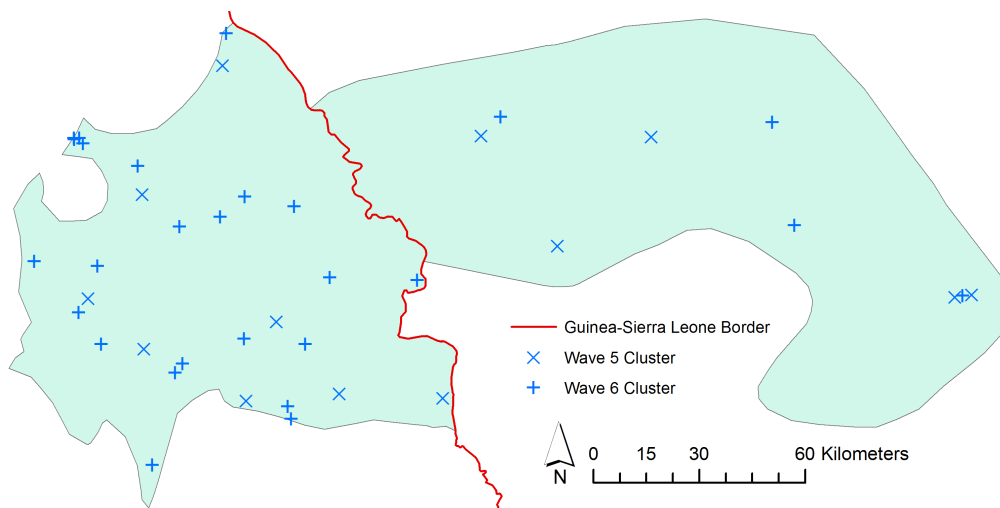

This figure documents the spatial distribution of DHS enumeration clusters in the partitioned Kuranko language group in Sierra Leone (west of the border) and Guinea (east of the border). Variation between individual and locational lexicostatistical similarity comes from the 40 percent of respondents who identify with an ethnolinguistic group different than the Kuranko.

measure locational and individual linguistic similarity to the national leader in year $t - 1$. See Appendix A for a list of countries and a detailed discussion of all DHS data.

The result is 33 DHS country-waves, 13 countries and 11 country pairs, with 20 partitioned language groups. Having at least 2 consecutive survey waves for each partitioned group allows for a set-up similar to my benchmark model, where within-group time variation comes from leadership changes across waves. One important difference from my benchmark set-up is that for 3 countries I only observe a single partitioned language group, meaning that country-location-language fixed effects are not applicable in this context.

Among the 56,455 respondents for whom I successfully match both locational and individual languages, I find that 55.9 percent reside in their ethnolinguistic homeland.[18] This finding corroborates the implicit assumption made in the regional-level analysis that the majority of a language region's inhabitants are native to that region. At the same time, having 44.1 percent of respondents be non-native to their location provides unique variation in individual and locational similarity resulting from leadership changes. I use this variation to separately estimate individual and locational similarity.[19]

---

[18]Nunn and Wantchekon (2011) also find that 55 percent of respondents in the 2005 Afrobarometer reside in their ethnolinguistic homeland. The consistency across datasets is quite remarkable since only 7 out of the 13 countries used in this paper overlap with the Afrobarometer data in Nunn and Wantchekon (2011).

[19]The use of non-natives in this way is methodologically similar to Nunn and Wantchekon (2011) and Michalopoulos et al. (2016), who also use variation within non-native Africans to disentangle regional effects from individual-level effects.

Consider, as an example, the Kuranko language group partitioned across Guinea and Sierra Leone. Figure 5 depicts the spatial distribution of Kuranko survey clusters by wave. For each survey respondent living in one of these clusters I assign the Kuranko language as their locational language, despite the fact that only 60.1 percent of respondents report Kuranko as their ethnolinguistic identity. Among the remaining 39.9 percent of respondents in the Kuranko region there are 9 other reported ethnolinguistic identities. Take the 117 Sierra Leoneans living in the Kuranko region who identify as Themne – the ethnicity/language of president Ernest Bai Koroma. The inclusion of individual similarity allows me to ask if Themne respondents benefit from coethnicity – and similarity more generally – irrespective of where they live.

3 Empirical Methodology

3.1 Identification of Linguistic Similarity

For the purpose of identification, I study groups partitioned across national borders. This empirical design is motivated by two facts: the ethnolinguistic identity of a national leader varies by country, and each partitioned group is split between two or more countries. This implies that within-group variation in similarity to each leader is coming from the placement of national borders, which were arbitrarily drawn by Europeans during the Scramble for Africa (Michalopoulos and Papaioannou, 2016).[20] The use of quasi-random borders for estimation is similar to Michalopoulos and Papaioannou (2014), though a key difference is that I construct a panel of partitioned groups rather than a cross-section, so the similarity of a group also varies across time as new ethnic leaders come to power.

The basic idea behind the identification strategy can be illustrated by constructing a triple-difference estimate using means of the raw night lights data. For this exercise, I discretize lexicostatistical similarity by separating groups into "similar" and "not similar" groups, where similar is defined as any group above the 75th percentile of linguistic similarity. Table 1 reports night light means for the treated and control groups, which I have separated into similar and not-similar groups both before and after treatment (leadership changes).[21]

---

[20]The use of arbitrarily straight lines prevailed when drawing borders in Africa because the Berlin Conference of 1884-85 legitimized claims of colonial sovereignty without pre-existing territorial occupation, rendering knowledge of pre-colonial group boundaries inconsequential (Englebert et al., 2002). The result was a reluctance by colonialists to respect these traditional boundaries when drawing borders (Herbst, 2000). Evidence of this is still seen today, where group partitions do not correlate with geography and natural resources (Michalopoulos and Papaioannou, 2016) and nearly 80 percent of all African borders follow lines of latitude and longitude – an amount larger than any other continent in the world (Alesina et al., 2011).

[21]To construct the dataset for this exercise I had to duplicate observations from my benchmark sample that can be classified as both "before" and "after" a leadership change at the same point in time. For example,

Table 1: Night Light Means Before-After Leader Change by Similar and Treated Groups

	Treated partition (leadership change)		Control partition (no leadership change)	
	Similar	Not similar	Similar	Not similar
(1) Before leadership change	0.226 (0.066)	0.066 (0.013)	0.179 (0.052)	0.079 (0.024)
(2) After leadership change	0.365 (0.121)	0.076 (0.018)	0.192 (0.055)	0.080 (0.024)
(3) Row(2) − Row(1)	0.139 (0.061)	0.010 (0.009)	0.013 (0.013)	0.002 (0.006)
(4) Similar(3) − Not similar(3)	0.129 (0.063)		0.011 (0.014)	
(5) Treated(4) − Untreated(4)	0.118 (0.060)			

Standard errors are clustered at the country-group level and are reported in parentheses.

Similar groups have much higher night lights at baseline than not-similar groups. This could reflect the fact that leaders tend to come from more developed regions of a country. This might also reflect past favoritism towards similar groups. In the regression analysis, these baseline differences are inconsequential: estimates reflect changes in night lights, and country-group fixed effects account for time invariant differences across groups. Robustness checks also confirm that group-level changes in economic activity immediately prior to a leadership change cannot explain away differences in lights based on similarity.

Row (3) compares the mean level of night lights before and after a leadership change for each of the four groups. Although mean night lights increase for all groups, the increase is small and insignificant for all but the treated-similar group. This finding reflects the fact that changes in leadership only impact groups directly exposed to the leadership change, i.e., the relevant source of variation. The fact that similar groups benefit over not-similar groups also foreshadows the empirical evidence of ethnic favoritism presented in Section 4. Relative

---

Malam Bacai Sanhá replaced João Bernardo Vieira as president of Guinea-Bissau in 1999, and Kumba Ialá replaced Malam Bacai Sanhá in 2000. The problem here is that every 1999 observation is an "after" group for Malam Bacai Sanhá's transition to government and a "before" group for Kumba Ialá's transition. Similarly, it is problematic that some observations act as both "control" and "treated" at different points in sample. I overcome these challenges by duplicating observations such that each observation in the augmented dataset uniquely identifies a group for each possible combination of before/after, control/treated and similar/not similar. Means are calculated as 5-year averages before and after a leadership change, though the results are quite similar when using a shorter timescale.

Table 2: Leadership Changes and Years in Office by Regions

	Leadership Changes	Ethnic Transitions	Number of Countries	Years of Incumbency by Leader		
				Min	Median	Max
West Africa	34	29	14	1	6	38
East Africa	12	8	10	2	10	34
Middle Africa	5	4	7	4	17	35
Southern Africa	8	3	4	2	7	18

to the sample mean of 0.123, the 0.139 increase in mean lights is quite substantial too.

Row (4) highlights a similar point with the difference in these differences: that a significant increase in night lights between similar and not-similar groups is only observed among the treated partitions. The lack of any significant change between control groups implies that, in the absence of a leadership change, the increase in night lights is not systematically different for similar and not-similar groups – a key identifying assumption.

The difference-in-differences control group estimate of 0.011 captures the differential growth in night lights among similar groups, relative to not-similar groups, that is not the result of a leadership change. The tripe-difference estimate, shown in row (5), assumes that a treated group receives the same similar-specific shock over and above the effect of treatment by difference out the excess growth of 0.011 in mean night lights. Accounting for these shocks yield a total change in night lights of 0.118, a slightly more conservative estimate than that reported difference-in-differences treatment group estimate of 0.129.

Leadership Changes

In my benchmark sample, the source of variation driving my results comes from 59 leadership changes – 44 of which reflect an ethnic transition in leadership and thus a change in linguistic similarity. Table 2 reports these numbers by region. The bulk of the variation in my data comes from West Africa, where 29 out of the 44 ethnic transitions take place. The extent of this variation is driven by the fact that the median leader holds office for only 6 years in West Africa. In East Africa the median leader holds office for 10 years, where there are a total of 8 ethnic transitions in office. In Middle Africa there are just 4 ethnic transitions, in part because there are fewer countries, but largely due to the fact that the median ruler holds office for 17 years. On the other hand, Southern Africa has only 3 ethnic transitions even though their median ruler has held office for just 7 years. The lack of ethnic transitions relative to the regions 8 leadership changes is mostly driven by the ethnic homogeneity of

Figure 6: Night Lights Before-After Leadership Change
Panel A

Panel B

This figure plots the average residual variation in night lights net of country-year fixed effects for three subsamples: those groups that experience a positive change in similarity following a leadership change (Panel A), those groups that experience a negative change in similarity (Panel B) and those groups that do not experience a change in similarity.

Lesotho, where over 99 percent of the population identify as Basotho. Table A4 provides a complete list of these leadership changes, including the timing and place of each change.

Yet even among regions with relatively few ethnic transitions, the observable variation in the data is quite large. The inclusion of group-year fixed effects implies that an ethnic transition in one country varies the mean similarity of a partition in that country and all other subgroups of that partition in neighbouring countries. In other words, the relative similarity within a partitioned group varies when any subgroup of a partition is exposed to a transition. This amounts to 382 unique relative similarities observed over the sample period.

To get a sense of how night lights respond to leadership changes, I plot the average residual variation in night lights net of country-year fixed effects in Figure 6 for three subsamples: those groups that experience a positive change in similarity following a leadership change (Panel A), those groups that experience a negative change in similarity (Panel B) and those groups that do not experience a change in similarity (both panels). The fact that night lights tend to mirror changes in linguistic similarity is consistent with the argument put forth in this paper: a group's well-being is increasing in their similarity to the national leader. This suggests that changes in night lights provide sufficient variation to detect patterns of favoritism following a leadership change, an observation consistent with Table 1. At the

same time, there is little difference in variation across subsamples prior to the change in leadership, which also suggests that the common trends assumption holds.[22]

3.2 Empirical Model

The main objective of this empirical analysis is to test the hypothesis that ethnic groups are better off the more linguistically similar they are to their national leader. To do this I estimate a triple difference-in-differences fixed effects model:

$$y_{c,l,t} = \gamma_{c,l} + \lambda_{c,t} + \theta_{l,t} + x'_{c,l,t}\,\Phi + \beta LS_{c,l,t-1} + \varepsilon_{c,l,t}. \tag{1}$$

The dependent variable $y_{c,l,t}$ is the night lights measure of economic activity for group l in country c in year t. As the dependent variable I follow the literature and take the afore-mentioned log transformation of night lights such that $y_{c,l,t} \equiv \ln\big(0.01 + \text{NightLights}_{c,l,t}\big)$.

$LS_{c,l,t-1}$, the variable of interest, measures the linguistic similarity between ethnolinguistic group l in country c and the ethnolinguistic identity of country c's political leader in year $t-1$. I lag linguistic similarity because of an expected delay between the decision to allocate public funds to a region and the actual allocation of those goods, and an expected delay between the actual allocation of public funds and the resulting regional increase in night light production.

$x_{c,l,t}$ is a vector of controls including the (logged) average of population density for each group, and the (logged) geodesic distance between the homeland of language group l and the homeland of the language group associated with the leader of country c. I also include a variety of geographic endowment controls in $x_{c,l,t}$: two indicator variables for the presence of oil and diamond reserves in both the leader and language group regions, as well as the absolute difference in elevation, ruggedness, precipitation, average temperature and Galor and Ozak's (2016) Caloric Suitability Index. These additional controls account for the possibility that national projects that are beneficial to the leader's region because of a particular geographic characteristic might also benefit other regions of similar character (Appendix A reports summary statistics and sources for all variables).

$\gamma_{c,l}$ difference out country-specific group effects common across time, $\lambda_{c,t}$ difference out country-specific time effects common across groups and $\theta_{l,t}$ difference out time-varying group effects common across countries. Together this set of fixed effects only allow for time variation in night lights at the country-group level. An estimate of β is an estimate of how variation in similarity – coming from leadership changes – impacts this time variation in night lights

---

[22]For this exercise I use the same augmented dataset that I use to produce Table 1 (see footnote 21).

at the country-group level.[23]

4   Empirical Results

Table 3 reports nine different estimates: three versions of equation (1) for each of the three linguistic similarity measures. For each measure of similarity, I report estimates (i) without any covariates (columns 1-3), (ii) estimates that control for log population density and the logged geodesic distance between each partitioned group and the corresponding leader's group (columns 4-6), and (iii) the full set of covariates I outlined in Section 3 (columns 7-9). Hereafter I will refer to columns 7-9 as my benchmark specification. Table D1 in the Appendix reports the estimates for various other fixed effects specifications.

Consistent with my hypothesis of ethnolinguistic favoritism, all nine coefficients are positive and my preferred measure of lexicostatistical similarity is always statistically significant. Because variation is coming from changes in the ethnic identity of a leader, the interpretation of these findings is that a group's well-being is increasing in their ethnic similarity to the leader. To give economic meaning to these estimates, consider the benchmark estimate of lexicostatistical similarity in column 7. Using the rule of thumb that the estimated elasticity of GDP per capita with respect to night lights is 0.3 (Henderson et al., 2012), the point estimate of 0.305 implies that a standard deviation increase in linguistic similarity (23 percent change) yields a 2.1 percent increase in regional GDP per capita, an economically significant effect.[24]

I also provide estimates for cladistic similarity and coethnicity to see how these alternative measures compare to lexicostatistical similarity. For my benchmark estimates both coefficients are positive and statistically significant, albeit only at the 10 percent level. Notice that in all iterations of equation (1), the magnitude and precision of the estimate is monotonically increasing in the measured continuity of linguistic similarity. This suggests that the observable variation among non-coethnic groups assists in identifying patterns of ethnic favoritism in Africa, and thus speaks the virtue of the lexicostatistical measure.

Table 4 reports estimates from a series of horse race regressions. With these estimates I show that the lexicostatistical measure is better at identifying patterns of favoritism than the alternative measures of similarity. In columns 1-4, I report estimates for all possible

---

[23]In my benchmark sample $\gamma_{c,l}$ represents 355 fixed effects, $\lambda_{c,t}$ represents 691 fixed effects and $\theta_{l,t}$ represents 3044 fixed effects. Because the sample has only 35 countries, I choose not to adjust standard errors for two-dimensional clustering within language groups and countries (Cameron et al., 2011). While the benchmark results are qualitatively similar when two-way clustering, I follow Kezdi's (2004) rule of thumb that at least 50 clusters are needed for accurate inference.

[24]The percentage change in GDP per capita $\approx$ percentage change in night lights $\times 0.3 = (\beta \times \Delta LS_{c,l,t-j}) \times 0.3 = 0.305 \times 0.230 \times 0.3 = 2.1\%$, assuming that $\ln(0.01 + \text{nightLights}_{c,l,t}) \approx \ln(\text{nightLights}_{c,l,t})$.

This table reports benchmark estimates associating each measure of linguistic similarity with night light luminosity for the years $t = 1992 - 2013$. Average night light luminosity is measured in language group l of country c in year t, and linguistic similarity measures the similarity between each language group and the ethnolinguistic identity of country c's leader in year $t - 1$. Lexicostatistical similarity is a continuous measure of a language pair's phonological similarity and is measured on the unit interval. Cladistic similarity is a discrete measure of similarity representing a language pair's ratio of shared branches on the Ethnologue language tree. Coethnic is binary measure of linguistic similarity that takes a value of 1 when language group l is also the ethnolinguistic identity of country c's leader. Distance & population density measure the log distance between each country-language group and the leader's ethnolinguistic group, and the log population density of a country-language group, respectively. The geographic controls include the absolute difference in elevation, ruggedness, precipitation, temperature and the caloric suitability index between leader and country-language group regions, in addition to two dummy variables indicating if both region contains diamond and oil deposits. Standard errors are clustered at the country-language group level and are reported in parentheses. * p < 0.10, ** p < 0.05, *** p < 0.01.

Observations	6,610	6,610	6,610	6,610	6,610	6,610

This table reports horse race regressions comparing each measure of linguistic similarity. Average night light luminosity is measured in language group l of country c in year t, and linguistic similarity measures the similarity between each language group and the ethnolinguistic identity of country c's leader in year $t-1$. Lexicostatistical similarity is a continuous measure of a language pair's phonological similarity and is measured on the unit interval. Cladistic similarity is a discrete measure of similarity representing a language pair's ratio of shared branches on the Ethnologue language tree. Coethnic is binary measure of linguistic similarity that takes a value of 1 when language group l is also the ethnolinguistic identity of country c's leader. Non-coethnic lexicostatistical similarity and Non-coethnic cladistic similarity are constructed by interacting a dummy variable for non-coethnicity with Lexicostatistical similarity and Cladistic similarity, respectively. All control variables are described in Table 3. Standard errors are clustered at the country-language group level and are reported in parentheses. * p < 0.10, ** p < 0.05, *** p < 0.01.

pairings of the three measures of similarity. Because all three measures of similarity are highly correlated with each other, and for coethnic observations are equivalent, the effect of lexicostatistical and cladistic similarity are estimated off of the additional variation these measures provide among non-coethnics. In all pairings the additional lexicostatistical variation is estimated to be statistically significant, despite the fact that the effect of coethnicity is not identifiable in these regressions. In column 3, cladistic similarity outperforms coethnicity in magnitude and precision, reaffirming the value of the addition variation it provides over a coethnic indicator, but neither are significantly different than zero.

To disentangle the effect of coethnicity from the benefits of similarity among non-coethnics, I define non-coethnic lexicostatistical similarity as $(1-\text{coethnic}_{t-1})\times$ lexicostatistical similarity, and equivalently for non-coethnic cladistic similarity. In other words, these non-coethnic similarity measures are equal to zero when the observed language group is coethnic to their national leader, and otherwise equivalent to the respective measure of similarity. Combined with the coethnic measure, I can exploit the same variation I identify off of in columns 2 and 3 but load the effect of coethnicity onto the coethnic dummy variable.

Because it is intuitive that a leader is more inclined to favor her coethnics, I expect to see a strong significant effect of coethnicity beyond the effect found among non-coethnic groups. Indeed, column 5 indicates that coethnics are most favored with an estimated increase of 0.260 in average night light luminosity. While there is still an observable benefit from similarity among non-coethnics, the magnitude of the effect is roughly one quarter the size of the coethnic effect on average. With a sample mean of 0.146, non-coethnic lexicostatistical similarity yields an average increase of 0.069 $(= 0.146 \times 0.473)$ in luminosity.[25]

I repeat this exercise with non-coethnic cladistic similarity and report the estimates in column (6). Once again I find the corresponding estimate for cladistic similarity from column (3) but can now identify the effect of coethnicity. The estimated coefficient for coethnicity is quite similar to the coethnic effect found in column (5), only now the additional variation coming from the cladistic measure is not enough to identify the effect of similarity among non-coethnic groups.

Taken together the results of Table 3 and Table 4 indicate that favoritism is most prominent among coethnics but also to a lesser extent among non-coethnics. These results also indicate that a continuous measure of lexicostatistical similarity provides valuable information that is not observable with a coethnic indicator variable. For the remainder of this section I proceed to test the robustness of the benchmark lexicostatistical estimate.

---

[25]By these estimates the threshold value of non-coethnic similarity is 0.550, above which would imply non-coethnics are better off than coethnics. The likelihood of measurement error in linguistic similarity implies this is a rather "fuzzy" threshold, and with only 2 percent of the benchmark sample above this threshold I find this result to be reassuring.

Table 5: Testing for Anticipatory Effects: Estimates Using Leads and Lags

		Dependent Variable: $y_{c,l,t} = \ln(0.01 + NightLights_{c,l,t})$

Observations	6,610	6,402	5,940	6,315	5,641

This table reports a series of tests for anticipatory effects in the benchmark estimates. Average night light intensity is measured in language group l of country c in year t, and Lexicostatistical similarity is a continuous measure of language group l's phonological similarity to the national leader and is measured on the unit interval. The same log transformation of the dependent variable is used for the lagged value of night lights, i.e., $\ln(0.01 + \text{nightLights}_{c,l,t-1})$. All control variables are described in Table 3. Standard errors are clustered at the country-language group level and are reported in parentheses. * p < 0.10, ** p < 0.05, *** p < 0.01.

Anticipatory Effects

In this section I test the common trends assumption underlying my benchmark estimates. Column (1) of Table 5 reproduces the benchmark estimate of lexicostatistical similarity for comparison. In columns (2) I report estimates of the benchmark model that include contemporaneous lexicostatistical similarity. Both measures of similarity are significant, though the estimated effect of contemporaneous similarity is noisier than lagged similarity – a finding that supports my decision to lag lexicostatistical similarity.

Column (3) reports estimates that also include a lead measure of lexicostatistical similarity as a direct test for anticipatory effects. Should there be any pre-trends in the incoming leader's group, then this lead measure of lexicostatistical similarity should be estimated significantly difference than zero. I find no evidence of a pre-trend, which is reassuring for identification that the common trends assumption is satisfied. The finding of no anticipatory changes in night lights is also consistent with Figure 6

Next I re-estimate equation (1) with a lagged dependent variable. Identification rests on the assumption that leaders are not endogenously elected because of the economic success of their ethnolinguistic group prior to an election. I find no evidence of this as indicated by column (4) and (5). Lexicostatistical similarity is estimated to be positive and significant at the 5 percent level, albeit with a reduced magnitude. Hence, these results are reassuring that my benchmark estimates are not an outcome of any pre-transition changes in economic activity in a leader's ethnolinguistic group.

Migration

One additional concern with my identification strategy is cross-border migration. Suppose individuals who live near the border become coethnics of the neighboring country's leader. These individuals may choose to migrate in response to this spatial disequilibrium of similarity. While the cultural affinity of partitioned groups might encourage cross-border migrations, Oucho (2006) points out that migration restrictions throughout sub-Saharan Africa make this unlikely in a formal capacity. To test for this I regress log population density on linguistic similarity in period $t-1$ and report the estimates in Table 6. If people are in fact migrating in response to leadership changes, I should observe corresponding changes in population density. These estimates also account for the possibility of within-country migration. In all specifications, the various measures of similarity are insignificant. Overall these estimates imply that changes in night lights within a partitioned group cannot be explained by movements of people to regions that are similar to the leader in terms of ethnolinguistic identity.

Table 6: Test for Migration Following Leadership Changes

	(1)	(2)	(3)

Language groups	163	163	163
Adjusted R^2	0.999	0.999	0.999
Observations	6,610	6,610	6,610

This table reports estimates associating population density with linguistics similarity as a test for changes in population density following a change in a leader's ethnolinguistic identity. Lexicostatistical similarity is a continuous measure of a language pair's phonological similarity and is measured on the unit interval. Cladistic similarity is a discrete measure of similarity representing a language pair's ratio of shared branches on the Ethnologue language tree. Coethnic is binary measure of linguistic similarity that takes a value of 1 when language group l is also the ethnolinguistic identity of country c's leader. Standard errors are clustered at the country-language group level and are reported in parentheses. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

What Drives Favoritism?

In this section I test for heterogeneity across a variety of potential channels to better understand what drives favoritism. First, I examine whether the extent of favoritism is a function of time a leader has held office. Table 7 reports these results. Column (1) reports estimates of an augmented equation (1) that includes an interaction between linguistic similarity and the number of the years a leader has held office. The interaction term enters positive and statistically significant, indicating that favoritism is an increasing function of the years a leader has held office.

I also construct a set of indicator variables at 5-year intervals to explore this further. Column (2) reports these estimates. All coefficients are positive and the magnitude of effect is increasing in the length of tenure, however there is no significant effect associated with the first five leaders of leadership. Taken together, Table 7 indicates that the extent of

Adjusted R^2	0.926	0.926
Observations	6,610	6,610

This table reports estimates of the dynamics of ethnolinguistic favoritism. The unit of observation is a language group l in country c in the specified year. Average night light intensity is measured in language group l of country c in year t, and Lexicostatistical similarity is a continuous measure of language group l's phonological similarity to the ethnolinguistic identity of the national leader. All control variables are described in Table 3. Standard errors are clustered at the country-language group level and are reported in parentheses. * p < 0.10, ** p < 0.05, *** p < 0.01.

ethnolinguistic favoritism is an increasing function of a leader's incumbency. In a continent where multi-decade presidencies are not uncommon (e.g., Jose Eduardo dos Santos in Angola or Robert Mugabe in Zimbabwe), it should come as no surprise that favoritism is so rampant.

I also check for heterogeneous effects across seven other measures: the level of democracy (Padro i Miquel, 2007; Burgess et al., 2015), language group Ethnologue population shares (Francois et al., 2015), distance to the capital from a group's centroid (Michalopoulos and Papaioannou, 2014), distance to the nearest coast from a group's centroid (Nunn, 2008; Nunn and Wantchekon, 2011), presence of an oil reserve and diamond mine within the territory of the country-language group (Jensen and Wantchekon, 2004). This analysis reveals little evidence of heterogeneity. See Table D2 in the appendix for these results.

Robustness Checks

I also show that the results are robust to a variety of specifications and estimators. I report and discuss each robustness check in Appendix D.

- I reproduce my benchmark estimates with additional controls for malaria and land suitability for agriculture. Because these data are only available at a $0.5° \times 0.5°$ spatial resolution (approx. 111 km × 111 km), I exclude them from my benchmark estimates to avoid losing observations where a pixel is larger than a language group partition (Table D3).

- To address the possibility of sample selection, I show that there is no difference in night lights and cladistic similarity between in- and out-of-sample partitions (Table D4).

- I check that measurement error resulting from the ambiguous assignment of a leader's ethnolinguistic identity does not explain my benchmark results, particularly the finding that favoritism exists among non-coethnics (Table D5).

- I reproduce my benchmark estimates on a balanced panel of 84 ethnolinguistic groups partitioned across 23 countries (Table D6).

- I re-estimate equation (1) and weight the estimates by the Ethnologue population of each language group to correct for possible heteroskedasticity (Table D7).

- I also provide estimates with two alternative transformations of the night lights data to show that my benchmark lexicostatistical estimate is not an outcome of the aforementioned log transformation (Table D8).

5 How Is Patronage Distributed?

In this section I use individual-level data from the Demographic and Health Survey (DHS), as outlined in Section 2.4, for two purposes: using a similar source of variation with different data serves as an additional robustness check of my benchmark analysis, and these data also allow me to explore how patronage is distributed. In particular, I use data on an individual's self-reported ethnolinguistic identity and the identity attached to the region where each respondent lives to construct two measures of lexicostatistical similarity: locational and individual similarity. I use these measures to test whether the benefits of ethnic similarity are exclusive to individuals living in their ethnic homeland, or if patronage distributed more broadly by targeting ethnically similar individuals irrespective of their location.

5.1 Locational and Individual Similarity Estimates

I test the general importance of locational and individual similarity vis-à-vis changes in the DHS wealth index – a composite measure of cumulative living conditions for a household. The index is constructed using data on household ownership of assets (e.g., television, refrigerator, telephone, etc.) and access to public resources (e.g., water, electricity, sanitation facility, etc.). Since variation in linguistic similarity comes from leadership changes, a positive estimate for either similarity measure implies better access to public resources and more acquired assets because of an individual's similarity across the significant dimension. I test the significance of these channels with the following empirical specification:

$$y_{i,l,e,c,t} = \alpha\, LOC_{l,c,t} + \beta\, IND_{e,c,t} + x'_{i,l,e,c,t}\, \Omega + \gamma_{c,t} + \lambda_{l,t} + \theta_{e,t} + \varepsilon_{i,l,e,c,t}. \tag{2}$$

The dependent variable, $y_{i,l,e,c,t}$, reflects the wealth index of individual i that self-identifies with ethnolinguistic group e and resides in the partitioned ethnolinguistic region l of country c during survey wave t. $x_{i,l,e,c,t}$ is a vector of individual characteristics. $LOC_{l,c,t}$, or locational similarity, measures the linguistic similarity of the partitioned region l to the national leader, whereas $IND_{e,c,t}$, or individual similarity, measures the linguistic similarity of an individual's self-reported identity e to the national leader, both of which vary by country c and survey wave t. Because 44.1 percent of respondents are non-native to the region where they reside, I can jointly estimate both channels to determine the relative importance of being similar to the leader versus living in a location with an attached identity similar to the leader. In every specification I include country-wave fixed effects ($\gamma_{c,t}$), locational language-wave fixed effects ($\lambda_{l,t}$) and individual language-wave fixed effects ($\theta_{e,t}$). I do not include country-language fixed effects because in some instances I only observe a single partitioned group in a country.

Table 8: Individual-Level Regressions: Locational and Individual Similarity

	(1)	(2)	(3)	(4)
		Dependent Variable: DHS Wealth Index

Clusters	88	88	88	88
Countries	13	13	13	13
Partitioned language groups	20	20	20	20
Adjusted R^2	0.605	0.605	0.605	0.605
Observations	56,455	56,455	56,455	56,455

This table reports estimates that test for favoritism outside of coethnic language partitions. The unit of observation is an individual. The individual set of control variables include age, age squared, rural indicator variable, a gender indicator variable and an indicator for respondents living in the capital city. Distance to the coast and border are in kilometers. Standard errors are in parentheses and adjusted for clustering at the country-language-wave level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Table 8 reports these estimates. In column 1 the estimate for lexicostatistical locational similarity is positive and significant at the 1 percent level. This point estimate of 0.540 is equivalent to 0.35 of a standard deviation increase in the wealth index. In column 2 I report the estimate for individual similarity. While the estimate has the expected positive sign, the coefficient is not precisely estimated. This suggests that changes in the individual-level wealth index are coming from transfers based on the ethnic identity of a region. Indeed,

when I run a horse race between the two, I find that locational similarity is significantly different than zero while individual similarity remains insignificant.[26]

Overall, these estimates indicate that favoritism operates through regional transfers, which suggests that individuals benefit from living in regions with an ethnic identity similar to their leader, even if they themselves are very dissimilar in their own ethnic identity. This finding is consistent with the evidence that Kenyan leaders invest twice as much in roads (Burgess et al., 2015), and disproportionately target school construction in their co-ethnic districts (Kramon and Posner, 2016). In a case study of Congo-Brazzaville, Franck and Rainer (2012) similarly find that ethnic divisions impact the patterns of regional school construction.

Finally, to show that the locational mechanism is not only driven by the coethnic effect, I separately estimate locational coethnicity and non-coethnic locational similarity. I do this in the same way I did in the regional-level analysis: I define non-coethnic locational similarity as $(1 - \text{coethnicity}) \times \text{locational similarity}$. Column 4 of Table 8 reports this estimate. I find that both the coethnic and non-coethnic effect are positive and strongly significant. These estimates suggest that the average level of non-coethnic locational similarity (0.164) yields an increase of 0.122 $(= 0.164 \times 0.742)$ in the wealth index – roughly one fourth the coethnic effect.

6   Discussion

The results of this paper indicate that ethnic favoritism is widespread throughout Africa, and that patronage is distributed to both the ethnic region of the leader and to related but non-coethnic regions. But what drives these regional transfers? Why might we expect to see favoritism outside of the leader's ethnic region?

I offer an explanation that relates to the literature on coalition building. Central to this literature is the idea that leaders respond to political instability by co-opting elites from outside of their ethnic group into high-level government positions to pacify unrest and to maintain control of the state (Joseph, 1987; Arriola, 2009; Francois et al., 2015). It is intuitive that the "closeness" of a group to the leader would predict their share in the governing coalition for reasons related to trust (Habyarimana et al., 2009), reduced costs of coordination (Miguel and Gugerty, 2005), clientelistic networks (Wantchekon, 2003) and more. Because leaders share power with ethnic groups other than their own to make credible their promise of patronage (Arriola, 2009), any evidence that leaders appoint closely related groups is an indication that coalition building is one mechanism underlying this paper's

---

[26]See Appendix D for the unconditional estimates.

findings.

An insightful paper by Francois et al. (2015) provides theoretical and empirical support for the claim that ethnic group representation in the governing coalition is proportional to a group's share of the national population. The logic of this theory runs contrary to ethnic favoritism: their proposed mechanism underlying coalition building is group size. Yet these authors still find that a leader's ethnic group receives a premium in government appointments over and above the effect of group size. While it is beyond the scope of this paper to take a stance on the relative importance of these channels, what is important is that they are not mutually exclusive to each other.

To shed light on this interesting area of research I document that the similarity of an ethnic group to the leader correlates with an ethnic group's representation in government *conditional* on group size. I use yearly data from Francois et al. (2015) on the share of an ethnic group's representation in the governing coalition for 15 African countries between 1992 and 2004.[27] The majority of Ethnologue groups are defined as Others in Francois et al.'s (2015) data, which severely limits the observable number of group partitions. Consequently, it is not possible to use the same source of within-group variation employed elsewhere in this paper. Instead I use an identical set-up to Francois et al. (2015), but augment their empirical model with an indicator variable for similar but not identical ethnic groups:

$$y_{c,e,t} = \alpha \, \text{coethnic}_{c,e,t} + \beta \, \text{similar}_{c,e,t} + f\left(\text{groupsize}_{c,e}\right) + \delta_c + \gamma_t + \epsilon_{c,e,t}. \tag{3}$$

The outcome variable $y_{c,e,t}$ is ethnic group e's share of cabinet positions in country c in year t. In addition to the usual $\text{coethnic}_{c,e,t}$ indicator variable, I include an indicator equal to one when a non-coethnic group's linguistic similarity is greater than a defined threshold of "closeness" (i.e., $\text{similar}_{c,e,t}$). Francois et al. (2015) find that $\text{groupsize}_{c,e}$ – the population share of ethnic group e in country c – is concave in its relationship with a group's share of cabinet positions, so I include $\text{groupsize}_{c,e}$ and its polynomial in all regressions. δ_c and γ_t capture unobserved time-invariant country effects and time trends. I follow Francois et al. (2015) and cluster standard errors at the country level.

I exploit a range of thresholds to let the data inform me of the relevant threshold of closeness. My preferred approach is to split the distribution of linguistic similarity for non-coethnics into deciles. I assign the threshold for closeness as any non-coethnic observation with similarity to the leader that is equal to or greater than a defined decile of the distribution. Hence, these thresholds are cumulative, where $\text{similar}_{c,e,t}$ is equal to one when a non-coethnic group's linguistic similarity is equal to or greater than the decile cut-off.[28]

---

[27]See Appendix D for details on the construction of this dataset.

[28]In Appendix D, I replicate Table III from Francois et al. (2015) and include the more general specification

Figure 7: Non-Coethnic Favoritism: $\hat{\beta}$ at Various Thresholds

Closeness Threshold: Deciles of Non-Coethnic Similarity
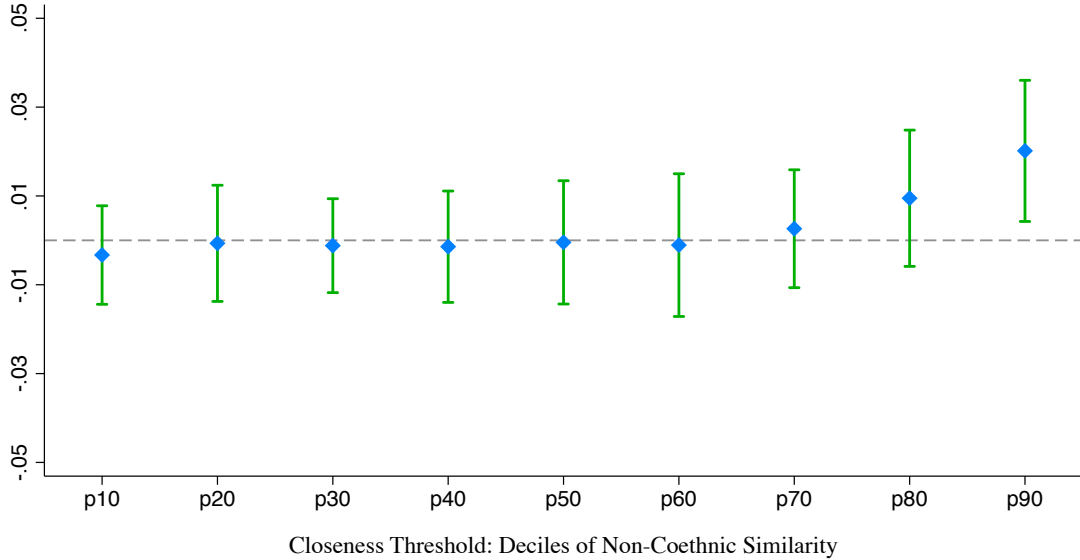

This figure plots point estimates of the $similar_{c,e,t}$ indicator variable in equation (3) at nine different closeness thresholds. Thresholds are set according to deciles of the distribution for non-coethnic similarity. These thresholds are cumulative, where $similar_{c,e,t}$ is equal to one when a non-coethnic group's linguistic similarity is equal to or greater than the decile threshold. Each estimate reflects the additional share of cabinet positions a similar non-coethnic group receives relative to non-similar non-coethnics. Intervals reflect 99% confidence levels.

I plot the point estimates of β in Figure 7 for each decile threshold, where the intervals reflect 99 percent confidence levels. The figure clearly documents non-coethnic favoritism in coalition building, at least among the stricter definitions of closeness. Because I include $coethnic_{c,e,t}$ and $similar_{c,e,t}$ in each regression, the estimate of β reflects the additional share of cabinet positions a similar non-coethnic group receives *relative* to other non-coethnics that do not satisfy the threshold level of similarity.

To assess the economic meaning of these estimates, I can compare the difference in a group's predicted outcome conditional on *mean* group size, after turning β on and off. Let the closeness threshold be the most stringent threshold at the 90th percentile of the distribution. I find that a non-coethnic group's share in the governing coalition jumps from 5.1 to 7.4 percent when β is included – a 45 percent increase.[29] The resulting share is almost 2 percentage points larger than the sample average share of 5.6 percent.

But how similar are these "close" groups? Consider the Gbe ethnolinguistic family, where

---

of lexicostatistical similarity in place of coethnicity.

[29]The point estimate for $similar_{c,e,t} = 0.023$, while the point estimates for group size and its polynomial are 1.225 and -1.795. For the mean non-coethnic group, the effect of group size is $5.1 = 1.225 \times 0.052 - 1.795 \times 0.007$, and 7.4 when adding the $similar_{c,e,t}$ premium.

three of the most widely spoken languages include Fon, Ewe and Gen. For the three possible pairings of these languages, the average lexicostatistical similarity is 46.8 percent. The mean similarity among non-coethnic groups in the 90th percentile of the distribution is 45.7 percent. This suggests that leaders appoint elites from outside of their immediate ethnic group that are part of the same family cluster. In other words, the affinity that similarity captures is reflective of the shared ancestry in a group's larger ethnic network.

Overall, these findings suggest that leaders are inclined to make ethnicity-based decisions when appointing ministers from outside their own ethnic group. While the estimates of equation (3) cannot necessarily be taken as causal, they are informative of the mechanism through which public resources are allocated to non-coethnic regions. The tendency of ministers to redirect funds to their coethnics explains why non-coethnic groups with representation in government receive patronage (Arriola, 2009).

7 Concluding Remarks

Ethnic favoritism is often thought to be endemic to African politics, yet the empirical basis for this claim is largely founded on single-country case studies. In this paper, I document evidence that ethnic favoritism is widespread throughout Africa using data for 35 sub-Saharan countries. I also introduce a novel measure of linguistic similarity that better predicts patterns of ethnic favoritism with added variation in measured similarity. The continuity of this measure enables the study of favoritism among groups that are not coethnic to the leader. This deepens our understanding of the *extent* of favoritism – evidence of favoritism among non-coethnics normally goes undetected when using a coethnic dummy variable. I also show that patronage tends to be distributed at a regional level rather than as targeted transfers towards individuals. I interpret these results through the lens of coalition building and find that ethnicity is one of the guiding principles behind high-level government appointments.

These observations inform policy in a number of new ways. In particular, my findings are informative of both the extent of favoritism and where it is expected to take place. This can be used for many purposes, one of which is to enhance monitoring of foreign aid. There is a growing body of evidence that links the misuse of foreign aid to ethnic patronage in Africa (Briggs, 2014; Jablonski, 2014). Greater oversight is achieved through a deeper understanding of where patronage is expected to flow. My findings suggest aid donors should not only worry about patronage directed toward the leader's ethnic group but also toward other related groups. The benefits of oversight are evident when comparing the non-interference aid policy of China with conditional transfers from the World Bank. Dreher et al. (2015) find little evidence that World Bank aid is used for patronage purposes

in contrast to the evidence that China's non-interference policy engenders resource allocation across ethnic lines rather than on a basis of need.

More generally, my findings speak to the value of nation-building policies that promote diversity in a Pan-Africanist tradition. Tanzania is a good example of a country that has stressed a sense of unity and shared history in its national policies. One nation-building tool of this type that is particularly relevant to this paper is Tanzania's national language policy (Miguel, 2004). In the mid-1960s, the Tanzanian government changed the official language of the country to Swahili. The extent to which Swahili is found in other countries and commonly used as a lingua franca speaks to the ethnic neutrality of the language. Within only a few years of its implementation, the official status granted to Swahili was described as a "linguistic revolution" for its ability to help shape a national consciousness that runs contrary to ethnic identity (Harries, 1969, p. 277). The Tanzania example is a model to be replicated elsewhere, given the evidence that ethnic favoritism is so widespread throughout Africa. This is not to imply that national language policies are the only means to pacify existing ethnic tensions: the lesson here is that national policies must be designed to engender acceptance of diversity through unity. For example, education is an effective way to build a national culture that actively values diversity and differences in experience and background.

Lastly, the findings of this paper call for future work. The evidence that favoritism is not simply a coethnic phenomenon demands a deeper understanding of what it means to be "close" to the ruling ethnic group. The taxonomy of linguistic and ethnic clusters provide an opportunity to study this notion of closeness in the same vein as Desmet et al. (2012). Linking the extent of favoritism to the impact it has on ethnic inequality is an important next step in this line of research. The Tanzania example also suggests ethnic favoritism is not an unavoidable consequence of a country's high level of diversity, an observation that is consistent with the literature on ethnic inequality. Why then do we observe favoritism in some countries and not others? Geographic segregation is linked to ethnic favoritism in Africa (Ejdemyr et al., 2014), while geographic endowments are linked to ethnic inequality (Alesina et al., 2016), which suggests an answer to this question lies at the intersection of these two areas of research.

FOR ONLINE PUBLICATION

A   Data Descriptions, Sources and Summary Statistics

A.1 Regional-Level Data Description and Sources

Country-language groups: Geo-referenced country-language group data comes from the World Language Mapping System (WLMS). These data map information from each language in the Ethnologue to the corresponding polygon. When calculating averages within these language group polygons, I use the Africa Albers Equal Area Conic projection.
Source: http://www.worldgeodatasets.com/language/

Linguistic similarity: I construct two measures of linguistic similarity: lexicostatistical similarity from the Automatic Similarity Judgement Program (ASJP), and cladistic similarity using Ethnologue data from the WLMS. I use these to measure the similarity between each language group and the ethnolinguistic identity of that country's national leader. I discuss how I assign a leader's ethnolinguistic identity in Section 2.3.
Source: http://asjp.clld.org and http://www.worldgeodatasets.com/language/

Night lights: Night light intensity comes from the Defense Meteorological Satellite Program (DMSP). My measure of night lights is calculated by averaging across pixels that fall within each WLMS country-language group polygon for each year the night light data is available (1992-2013). To minimize area distortions I use the Africa Albers Equal Area Conic projection. In some years data is available for two separate satellites, and in all such cases the correlation between the two is greater than 99% in my sample. To remove choice on the matter I use an average of both. The dependent variable used in the benchmark analysis is ln(0.01 + average night lights).
Source: http://ngdc.noaa.gov/eog/dmsp/downloadV4composites.html

Population density: Population density is calculated by averaging across pixels that fall within each country-language group polygon. To minimize area distortions I use the Africa Albers Equal Area Conic projection. Data comes from the Gridded Population of the World, which is available in 5-year intervals: 1990, 1995, 2000, 2005, 2010. For intermediate years I assume population density is constant; e.g., the 1995 population density is assigned to years 1995-1999. Throughout the regression analysis I use log population density.
Source: http://sedac.ciesin.columbia.edu/data/collection/gpw-v3

National leaders: I collected birthplace locations of all African leaders between 1991-2013. Names of African leaders and years entered and exited office comes from the Archigos Database on Leaders 1875-2004 (Goemans et al., 2009), which I extended to 2011 using data from Dreher et al. (2015), and 2012-2013 using a country's Historical Dictionary and other secondary sources.
Source: http://www.rochester.edu/college/faculty/hgoemans/data.htm

National leader birthplace coordinates: Birthplace locations are confirmed using Wikipedia, and entered into www.latlong.com to collect latitude and longitude coordinates.
Source: http://www.latlong.net

Years in office: To calculate each leader's current years in office and total years in office I use the entry and exit data described above.
Source: Calculated using Stata.

Distance to leader's birth region: Country-language group centroids calculated in ArcGIS, and the distance between each centroid and the national leader's birthplace coordinates is calculated in Stata using the `globdist` command. Throughout the regression analysis I use log leader birthplace distance.
Source: Calculated using ArcGIS and Stata.

Absolute difference in elevation: I collect elevation data from the National Geophysical Data Centre (NGDC) at the National Oceanic and Atmospheric Administration (NOAA). I measure average elevation of each partitioned language group and leader's ethnolinguistic group. To minimize area distortions I use the Africa Albers Equal Area Conic projection. I use Stata to calculate the absolute difference between the two.
Source: www.ngdc.noaa.gov/mgg/topo/globe.html

Absolute difference in ruggedness: As a measure of ruggedness I use the standard deviation of the NGDC elevation data. I use Stata to calculate the absolute difference between the two.
Source: www.ngdc.noaa.gov/mgg/topo/globe.html

Absolute difference in precipitation: Precipitation data comes from the WorldClim – Global Climate Database. I measure average precipitation within each partitioned lan-

guage group and leader's ethnolinguistic group using the Africa Albers Equal Area Conic projection. I use Stata to calculate the absolute difference between the two.
Source: http://www.worldclim.org/current

Absolute difference in temperature: Temperature data comes from the WorldClim – Global Climate Database. I measure the average temperature within each partitioned language group and leader's ethnolinguistic group using the Africa Albers Equal Area Conic projection. I use Stata to calculate the absolute difference between the two.
Source: http://www.worldclim.org/current

Absolute difference in caloric suitability index: I sourced the caloric suitability index (CSI) data from Galor and Ozak (2016). CSI is a measure of agricultural productivity that reflects the caloric potential in a grid cell. It's based on the Global Agro-Ecological Zones (GAEZ) project of the Food and Agriculture Organization (FAO). A variety of related measures are available: in the reported estimates I use the pre-1500 average CSI measure that includes cells with zero productivity. The results are not sensitive to which measure I use. I measure average CSI within each partitioned language group and leader's ethnolinguistic group using the Africa Albers Equal Area Conic projection. I use Stata to calculate the absolute difference between the two.
Source: http://omerozak.com/csi

Oil reserve: I construct an indicator variable equal to one if an oil field is found in both the partitioned language group and leader's ethnolinguistic group. Version 1.2 of the Petroleum Dataset contains geo-referenced point data indicating the presence of on-shore oil and gas deposits from around the world.
Source: https://www.prio.org/Data/Geographical-and-Resource-Datasets/Petroleum-Dataset/

Diamond reserve: I construct an indicator variable equal to one if a known diamond deposit is found in both the partitioned language group and leader's ethnolinguistic group. Version 1.2 of the Petroleum Dataset contains geo-referenced point data indicating the presence of on-shore oil and gas deposits from around the world.
Source: https://www.prio.org/Data/Geographical-and-Resource-Datasets/Diamond-Resources/

A.2 Individual-Level Data Description and Sources

Unless otherwise stated, all individual-level data comes from the Demographic and Health Surveys (DHS). Source: http://dhsprogram.com/

Individual linguistic similarity: To assign an individual a home language I assign the reported language a respondent speaks at home when this data is available (59 percent availability). For surveys when this data isn't available or the reported language is "other", I map the respondent's home language from their reported ethnicity. To do this I use the following assignment rule:

1. Direct match: the DHS ethnicity name is the same as an Ethnologue language name for the respondent's country of residence.

2. Alternative name: the unmatched DHS ethnicity is an unambiguous alternative name for a language in the Ethnologue or Glottolog database.

3. Macrolanguage: if the ethnicity corresponds to a macrolanguage in the Ethnologue, then I assign the most populated sub-language of that macrolanguage.

4. Population size: if the unmatched ethnicity maps to numerous languages, I choose the language with the largest Ethnologue population.

I also cross-reference the Wikipedia page for each ethnic group to corroborate that the assigned language maps into the reported ethnicity. Then using the same data on leaders as in the regional-analysis, I match the lexicostatistical similarity of the respondent's home language to the leader's ethnolinguistic identity.
Source: http://asjp.clld.org

Locational linguistic similarity: I project DHS cluster latitude and longitude coordinates onto the Ethnologue language map and assign the associated language as the regional language group to that respondent. In instances of overlapping language groups, I assign the largest group in terms of population. Then using the same data on leaders as in the regional-analysis, I match the lexicostatistical similarity of the respondent's home language to the leader's ethnolinguistic identity.
Source: http://asjp.clld.org

Wealth Index: I use the quantile DHS wealth index. The quantile index is derived from a composite measure of a household's assets (e.g., television, refrigerator, telephone, etc.)

and access to public resources (e.g., water, electricity, sanitation facility, etc.), in addition to data indicating if a household owns agricultural land and if they employ a domestic servant. Principal component analysis is used to construct the original index, then respondents are order by score and sorted into quintiles. Read the DHS Comparative Report: The DHS Wealth Index for more details.

Age: Age of respondent at the time of survey.

Gender: An indicator variable equal to one if a respondent is female.

Rural: An indicator variable for rural locations.

Education: The 10 education fixed effects are from question 90.

Religion: The 18 fixed effects for the religion of a respondent come from question 91.

Distance to the capital: I use the World Cities layer available on the ArcGIS website, which includes latitude-longitude coordinates and indicators for capital cities. I calculate language group centroids coordinates using ArcGIS, and measure the geodesic distance between the two points in Stata using the `globdist` command.
Source: http://www.arcgis.com/home/

Distance to the coast: I use the coastline shapefile from Natural Earth, calculate the nearest coastline from a language groups centroid using the Near tool in ArcGIS. I measure the geodesic distance between the two points in Stata using the `globdist` command.
Source: http://www.naturalearthdata.com/downloads/10m-physical-vectors/10m-coastline/

Distance to the border: I use country boundaries from the Digital Chart of the World (5th edition) that's complimentary to the Ethnologue data from the WLMS, and calculate the nearest border from a language groups centroid using the Near tool in ArcGIS. I measure the geodesic distance between the two points in Stata using the `globdist` command.

B Measures of Linguistic Similarity

B.1 Computerized Lexicostatistical Similarity

The computerized approach to estimating lexicostatistical distances was developed as part of the *Automatic Similarity Judgement Program* (ASJP), a project run by linguists at the Max Planck Institute for Evolutionary Anthropology. To begin a list of 40 implied meanings (i.e., words) are compiled for each language to compare the lexical similarity of any language pair. Swadesh (1952) first introduced the notion of a basic list of words believed to be universal across nearly all world languages. When a word is universal across world languages, its implied meaning, and therefore any estimate of linguistic distance, is independent of culture and geography. From here on I refer to this 40-word list as a Swadesh list, as it is commonly called.[30]

For each language the 40 words are transcribed into a standardized orthography called ASJPcode, a phonetic ASCII alphabet consisting of 34 consonants and 7 vowels. A standardized alphabet restricts variation across languages to phonological differences only. Meanings are then transcribed according to pronunciation before language distances are estimated.

I use a variant of the Levenshtein distance algorithm, which in its simplest form calculates the minimum number of edits necessary to translate the spelling of a word from one language to another. In particular, I use the normalized and divided Levenshtein distance estimator proposed by Bakker et al. (2009).[31] Denote $LD(\alpha_i, \beta_i)$ as the raw Levenshtein distance for word i of languages α and β. Each word i comes from the aforementioned Swadesh list. Define the length of this list be M, so $1 \leq i \leq M$.[32] The algorithm is run to calculate $LD(\alpha_i, \beta_i)$ for each word in the M-word Swadesh list across each language pair. To correct for the fact that longer words will often demand more edits, the distance is normalized according to word length:

$$LDN(\alpha_i, \beta_i) = \frac{LD(\alpha_i, \beta_i)}{L(\alpha_i, \beta_i)} \qquad (4)$$

where $L(\alpha_i, \beta_i)$ is the length of the longer of the two spellings α_i and β_i of word i. $LDN(\alpha_i, \beta_i)$ is the normalized Levenshtein distance, which represents a percentage estimate of dissimilarity between languages α and β for word i. For each language pair, $LDN(\alpha_i, \beta_i)$ is calculated

---

[30] A recent paper by Holman et al. (2009) shows that the 40-item list employed here, deduced from rigorous testing for word stability across all languages, yields results at least as good as those of the commonly used 100-item list proposed by Swadesh (1955).

[31] I use Taraka Rama's (2013) Python program for string distance calculations.

[32] Wichmann et al. (2010) point out that in some instances not every word on the 40-word list exists for a language, but in all cases a minimum of 70 percent of the 40-word list exist.

for each word of the M-word Swadesh list. Then the average lexical distance for each language pair is calculated by averaging across all M words for those two languages. The average distance between two languages is then

$$LDN(\alpha, \beta) = \frac{1}{M} \sum_{i=1}^{M} LDN(\alpha_i, \beta_i). \tag{5}$$

A second normalization procedure is then adopted to account for phonological similarity that is the result of coincidence. This adjustment is done to correct for accidental similarity in sound structure of two languages that is unrelated to their historical relationship. The motivation for this step is that no prior assumptions need to be made about historical versus chance relationship. To implement this normalization the defined distance $LDN(\alpha, \beta)$ is divided by the global distance between two language. To see this, first denote the global distance between languages α and β as

$$GD(\alpha, \beta) = \frac{1}{M(M-1)} \sum_{i \neq j}^{M} LD(\alpha_i, \beta_j), \tag{6}$$

where $GD(\alpha, \beta)$ is the global (average) distance between two languages excluding all word comparisons of the same meaning. This estimates the similarity of languages α and β only in terms of the ordering and frequency of characters, and is independent of meaning. The second normalization procedure is then implemented by weighting equation (5) with equation (6) as follows:

$$LDND(\alpha, \beta) = \frac{LDN(\alpha, \beta)}{GD(\alpha, \beta)}. \tag{7}$$

$LDND(\alpha, \beta)$ is the final measure of linguistic distance, referred to as the normalized and divided Levenshtein distance (LDND). This measure yields a percentage estimate of the language dissimilarity between α and β. In instances where two languages have many accidental similarities in terms of ordering and frequency of characters, the second normalization procedure can yield percentage estimates larger than 100 percent by construction, so I divide $LDND(\alpha, \beta)$ by its maximum value to normalize the measure as a continuous $[0, 1]$ variable. Finally, I construct a measure of lexicostatistical linguistic similarity as follows:

$$LS(\alpha, \beta) = 1 - LDND(\alpha, \beta). \tag{8}$$

B.2 Cladistic Similarity

Figure B1: Phylogenetic Tree of Eritrean Languages
This figure depicts the language tree for the 8 major languages of Eritrea. Because of the asymmetrical nature of language splitting, the number of branches varies among language families. To measure cladistic similarity it is necessary that all branches be extended to the lowest level of aggregation. To do this I assume all languages are equal distance from the proto-language at Level 0. Hence, the dashed lines depict the assumed relationship between the proto-language (Level 0) and all current Eritrean languages (Level 6).

To construct a measure cladistic similarity I first calculate the number of shared branches between language α and β on the Ethnologue language tree, denoted $s(\alpha, \beta)$. Let M be the maximum number of tree branches between any two languages. I then construct cladistic linguistic similarity as follows:

$$CS(\alpha, \beta) = \left(\frac{s(\alpha, \beta)}{M} \right)^{\delta},$$

(9)

where δ is an arbitrarily assigned weight used to discount more recent linguistic cleavages relative to deep cleavages. I describe this weight as arbitrary because there is no consensus on the appropriate weight to be assumed. Fearon (2003) argues the true function is probably concave and assumes a value of $\delta = 0.5$, which has since become the convention. Desmet et al. (2009) experiment with a range of values between $\delta \in [0.04, 0.10]$, but settle on a value of $\delta = 0.05$. In all reported estimates I assume $\delta = 0.5$, though the estimates are robust to alternative weighting assumptions (not shown here).

One issue with calculating cladistic similarity is the asymmetrical nature of historical language splitting. Because the number of branches varies among language families and

subfamilies, the maximum number of branches between any two languages is not constant. To overcome this challenge I assume that all current languages are of equal distance from the proto-language at the root of the Ethnologue language tree. I visualize this assumption in Figure B1, where I have constructed a phylogenetic language tree for the 8 distinct languages of Eritrea. The dashed lines represent this assumed historical relationship, so in all cases the contemporary Eritrean languages possess an equal number of branches to the proto-language at Level 0. Although $M = 6$ in Figure B1, in the Ethnologue language tree the highest number of classifications for any language is $M = 15$, which I abstract from here for simplicity.

B.3 Coethnicity

Coethnicity is a dummy variable that is equal to one when a partitioned group is the same ethnolinguistic group that a leader descends from, i.e., linguistic similarity is equal to one.

$$
\text{Coethnicity} = \begin{cases} 1 & \text{if linguistic similarity} = 1 \\ 0 & \text{otherwise} \end{cases} \tag{10}
$$

C Mapping Ethnicity to Language

There is mostly agreement between ethnographers that language is a suitable marker of ethnicity in Africa (Batibo, 2005; Desmet et al., 2017). The challenge of mapping ethnicity to language is that, in some instances, a single ethnic group speaks many languages. In such instances it's not obvious what language is the appropriate language to match to a leader's ethnicity. As a solution to this problem I use the following three-step assignment rule to construct a mapping between ethnicity and language in Africa.

Step 1: For each ethnic group, I refer to the Ethnologue list of languages for the country to which they belong. If a language name is identical to the ethnic name then I assign the corresponding language to that ethnicity.

Step 2: If there is no language name identical to the ethnicity then I check the alternate names for a language. If an ethnic name matches an alternate language name, I assign the corresponding language to that ethnicity.

Step 3: If a set of potential language matches still exist, I assign the largest language group (in terms of population) to the ethnic group.

D Supplementary Material

This section presents results referenced but not presented in the main body of the paper.

D.1 Various Fixed Effects Specifications

Table D1 reports 27 different estimates: 9 versions of equation (1) for each of the 3 linguistic similarity measures. Columns 1-3 report between-group estimates with country-year fixed effects, the estimates in columns 4-6 add country-language fixed effects, and columns 7-9 report estimates for the triple-difference estimator. For each set of three regressions I report estimates (i) without any covariates, (ii) estimates that only control for log population density and the logged geodesic distance between each partitioned group and the corresponding leader's group, and (iii) the full set of covariates I outlined in Section 3.

Consistent with my hypothesis of ethnolinguistic favoritism, all 27 coefficients are positive and the majority are statistically significant. In all cases my preferred measure of lexico-statistical similarity is significant with the exception of column 4, where lexicostatistical similarity has a reported p-value of 0.127. However, in this instance, the estimator lacks language-year fixed effects and thus does not exploit the counterfactual comparison of the same language group on the other side of the border.

Indeed, the addition of language-year fixed effects in 7-9 adds considerable precision to the estimates relative to columns 4-6. The allowance of a within-group estimator that comes from having a panel of partitioned language groups substantially improves my ability to identify ethnolinguistic favoritism.

I also provide estimates for cladistic similarity and coethnicity to see how these alternative measures compare to lexicostatistical similarity. For my benchmark estimates both coefficients are positive and statistically significant, albeit only at the 10 percent level. Not only does the estimated coefficient monotonically increase in the measured continuity of linguistic similarity, but lexicostatistical similarity is also more precisely estimated than both alternative measures. This suggests that the observable variation among non-coethnic groups assists in identifying patterns of ethnic favoritism in Africa.

D.2 Heterogeneity

The analysis reveals little evidence of heterogeneity (Table D2). One explanation for a lack of heterogeneity is that these different channels are only relevant in some countries and do not generalize to the 35-country sample I use here. Another possible explanation is that the rich set of fixed effects in each regression absorb much of the important variation. For

example, in column (1), I find that democracy has a mitigating effect on the extent of observed favoritism, but this effect is not statistically significant. While the intuition is consistent with Burgess et al. (2015), the lack of precision likely comes from the fact that country-year fixed effects account for the level effect of democracy, and the residual variation is not significant enough to identify any meaningful effect. A similar explanation applies to the remaining variables, where country-language fixed effects absorb the level effect for each because of the time invariance of these group-level measures.

However, there is some evidence of heterogeneity in terms of a diamond mine being present within a country-language group. The negative coefficient implies favoritism is less prevalent in regions where diamond mines exist. On interpretation is that the presence of diamonds creates wealth, and the resulting development may reduce the material importance of patronage to the region. Yet the lack of heterogeneity in oil reserves does not corroborate this story, so I leave a more concrete analysis of why diamond mines might constrain favoritism to future research.

D.3 Additional Controls

In this section I reproduce the benchmark estimates with two additional control variables: the Malaria Ecology Index (Kiszewski et al., 2004) and the Agricultural Suitability Index (Ramankutty et al., 2002). The trouble with these data is that in a number of instances a single raster cell covers an area larger than a country-language group partition because these data are only available at a spatial resolution of $0.5° \times 0.5°$ (approximately 111 km $\times$ 111 km). These partitions are dropped from group average calculations, resulting in a sample 61.5 percent of the benchmark sample size.

Table D3 reports these subsample estimates that include the additional control variables. For each of the three measures of similarity I report estimates that include the absolute difference in the Malaria Ecology Index, the absolute difference in the Agricultural Suitability Index and estimates that include both measures, in addition to benchmark set of controls. The results are unchanged by including these controls.

D.4 Sample Selection

My inability to observe the lexicostatistical similarity of the 64 language groups without an ASJP language list raises the question whether these unobserved groups are systematically different than those in my benchmark sample. To address this concern I test for mean differences in key observables and report these differences in Table D4.

First I show that there is no difference in the average night light luminosity between

in- and out-of-sample partitioned language groups. I also show that there is no difference between the cladistic similarity of in- and out-of-sample groups. These two results are reassuring that both sets of partitioned groups are comparable in terms of economic activity and proximity to their leader.

To the contrary, I show that in-sample groups reside in countries that are, on average, more democratic, more competitive politically, have more constraints on the executive, and are more open and competitive in the recruitment of executives. Should there be an in-sample selection bias, these institutional mean differences suggest that my estimates would be biased towards zero, given the evidence that a well-functioning democracy mitigates the extent of ethnic favoritism (Burgess et al., 2015) and regional favoritism (Hodler and Raschky, 2014)

D.5 Measurement Error

When an unambiguous assignment of a leader's ethnolinguistic identity cannot be made, I assign the group with the largest population among the set of potential matches. The finding that favoritism exists among groups that are not coethnic to the leader might be driven by the measurement error introduced by this approach.

In this section I report estimates on a subsample of my benchmark dataset that excludes the 4 leaders I could not unambiguously match.[33] Table D5 reports these results. Overall little is changed from my benchmark estimates, with the exception that coethnicity is no longer significant at standard levels of confidence. However, lexicostatistical similarity is roust to these excluded leaders, and most importantly, column (4) of Table D5 makes clear that the significance of non-coethnic similarity is not a consequence of the possible measurement error introduced when assigning an ethnolinguistic identity to the aforementioned leaders.

D.6 Balanced Panel

In this section I test the robustness of the benchmark estimates using a balanced panel of country-language groups between 1992 and 2013. My benchmark panel was unbalanced because of missing data on language lists used to estimate lexciostatistical similarity. This is problematic if these lists are missing for non-random reasons (Cameron and Trivedi, 2005). To check this I limit the analysis to a balanced sample of 84 language groups partitioned across 23 countries. Table D6 reports these estimates.

---

[33]Mobutu Sese Seko (DRC), Joseph Kabila (DRC), Laurent-Desire Kabila (DRC) and Goodluck Jonathan (Nigeria).

In all 27 reported regressions the measure of linguistic similarity takes the expected positive sign positive. For my preferred measure of lexicostatistical similarity the coefficients are statistically significant in all but one regression. The magnitudes of the estimates are also relatively similar to my benchmark estimates. To the contrary cladistic similarity seems to be quite sensitive to this subsample and in only significant in a single instance. The coethnic results are similar to those in Table 3.

D.7 Weighted Regressions

In this section I test for heteroskedasticity in my benchmark estimates by weighting regressions by the Ethnologue population of each language group. The idea is that the measure of night light intensity is an average within each country-language group, and it is likely to have more variance in places where the population is small (Solon et al., 2015). Table D7 reports these estimates.

The lexicostatistical estimates are less sensitive to weighting than the cladistic and coethnic estimates. While a few lexicostatistical estimates lose their significance in columns (4)-(6), these estimates do not exploit language-year fixed effects, and hence are not identified off the exogenous within-group variation. In my benchmark specification in column (9), the effect of lexicostatistical similarity is significant at the 5 percent level and very similar to the benchmark estimate in terms of magnitude.

D.8 Alternative Night Light Transformations

The log transformation used throughout the regional analysis is without a doubt arbitrary. The use of this transformation has become the convention when using these night lights data so I follow the literature in my choice to add 0.01 to the log transformation. Nonetheless, I experiment with two alternative transformations in Table D8.

In columns (1)-(3) I report estimates where the dependent variable is defined as the square root of the raw night lights data. In columns (4)-(6) I log the night lights data without adding a constant. The latter results in a substantial loss of observations due to the fact that 40 percent of the observations exhibit zero night light activity. Because I must observe a partitioned group on both sides of the border for any year, I lose nearly 60 percent of my benchmark sample using this log transformation.

I find that the lexicostatistical estimate is robust to both transformations, while the cladistic is only robust to the square root transformation. Coethnicity remains positive but loses its statistical significance is both instances.

D.9 First Differences

I report first difference estimates in Table D9. While I do find a positive coefficient for each measure of similarity, the majority of estimates fall just outside standard levels of confidence. This is due to the fact that there is less variation in changes of similarity over time than there is across groups in levels.

D.10 DHS Additional Tables

Table D12 reports 15 estimates: 5 separate specifications for both locational and individual similarity, and the same five specifications for the joint similarity estimates. In all specifications I adjust standard errors for clustering in country-wave-locational-language areas.

The top panel reports estimates for locational similarity. In column (1) the coefficient takes the expected positive sign, but is insignificant because the standard error is estimated to be quite large. However, in this specification I do not account for any individual characteristics, including whether a respondent lives in a rural location. Young (2013) shows that the urban-rural income gap accounts for 40 percent of mean country inequality in a sample of 65 DHS countries. In column (2) I report an estimate that includes a rural indicator variable. Indeed, the inclusion of this indicator substantially improves the precision of estimation, where locational similarity is now significant at the 1 percent level. In column (3) I add a set of individual controls.[34] The magnitude of locational similarity increases slightly and maintains its strong significant effect on individual wealth. In Table D12 I add each individual control variable one at a time. While I account for capital city effects with an indicator variable, I also account for additional spatial effects in columns (4) and (5) by separately adding the geodesic distance to the nearest coast and border.[35]

The middle panel of Table D10 reports estimates for individual similarity. While all coefficients take the expected positive sign, only a single estimate of individual similarity is statistically significant. When I do not control for any covariates the effect of individual similarity is very precisely estimated. To the contrary, the effect goes away once I account for respondents living in rural locations. The same is true when including the full set of controls.

Next I jointly estimate both channels using the aforementioned variation among individuals non-native to the region in which they reside. The results are consistent with the rest of the table and reported in the bottom panel of Table D10. In column (1) the estimate for

---

[34]The set of individual controls include age, age squared, a female indicator, a rural indicator, a capital city indicator, 5 education fixed effects and 7 religion fixed effects. See Appendix A for variable definitions.

[35]I include distances separately because language areas tend to be fairly small, so location clusters in a partition are usually very close together and distance measures are highly collinear.

individual similarity outperforms locational similarity when no individual characteristics are accounted for, however the reverse is true in columns (2)-(5) as covariates are incrementally added – in particular the rural indicator.

To show that the locational mechanism is not only driven by the coethnic effect, I separately estimate locational coethnicity and non-coethnic locational similarity. I do this in the same way I did in the regional-level analysis: I define non-coethnic locational similarity as $(1 - \text{coethnicity}) \times \text{locational similarity}$. Table D11 reports these estimates. While non-coethnic locational similarity is estimated to be no different than zero in the most basic regression, once again after the baseline set of controls are added both the coethnic and non-coethnic effect are positive and strongly significant. Using the more conservative estimates of column (5), this suggests that the average level of non-coethnic locational similarity (0.164) yields an increase of $0.094 (= 0.164 \times 0.573)$ in the wealth index – roughly one fourth the coethnic effect.

Finally, I also report the DHS estimates for locational similarity and include each baseline covariate one at a time. The idea here is to highlight the relative importance of controlling for the urban-rural inequality gap when using the DHS wealth index (Young, 2013). Table D12 reports these estimates.

Indeed I find that the precision of the locational similarity estimate is substantially improved by including an indicator variable for respondents living in rural regions. While many of the other covariates are themselves positive, no other variable have such a large confounding effect on locational similarity in its absence.

D.11 Coalition Building

Data

I use data from Francois et al. (2015) on the share of an ethnic group's representation in the governing coalition for 15 African countries.[36] These data are available at a yearly interval until 2004 for the ethnic groups listed in Alesina et al. (2003) and Fearon (2003). Because the unit of observation is an ethnic group, I assign an Ethnologue language group to each ethnicity using the assignment strategy outlined in Appendix C.[37] I measure the lexicostatistical similarity of these groups to the ethnolinguistic identity of the national leader

---

[36]Benin, Cameroon, Cote dIvoire, Democratic Republic of Congo, Gabon, Ghana, Guinea, Liberia, Nigeria, Republic of Congo, Sierra Leone, Tanzania, Togo, Kenya, and Uganda.

[37]For 87.5 percent of the 264 ethnic groups not listed as "Other", the name of the ethnic group unambiguously corresponds to an Ethnologue name or alternative name in the country in which the group resides. Only 12.5 percent of groups require I use population as a tie breaker when multiple languages can be mapped to an ethnicity. 51 of the assigned languages do not possess an ASJP language list and thus are dropped from the analysis.

between 1992 and 2004 using the leader data described in Section 2.3. In each country a residual ethnic categorization named Other is assigned to capture all groups outside of a country's major ethnic groups. Because Others lack a single ethnolinguistic identity, I assign Other groups a value of zero percent similarity to their leader.

Results

I report estimates of equation (3) in Table D13. Column 1 replicates the main estimate of Francois et al. (2015) on the subset of data that I observe lexicostatistical similarity. The coefficient for coethnicity takes the expected positive sign, implying there is a 9 percent increase in the leader's group share of the governing coalition over and above the ministerial appointments made in accordance with the leader's group size. The magnitude of this coefficient is slightly smaller than the comparable coefficient in Francois et al.'s (2015) Table III. This suggests that, if anything, this subsample biases the coefficient downward. Column 2 corroborates this result using lexicostatistical similarity in place of coethnicity. In column 3, I separate the effect of coethnicity from lexicostatistical similarity using the same approach I used in Section 4; i.e., non-coethnic similarity = $(1-\text{coethnicity})\times$lexicostatistical similarity. The reported estimates in column 3 confirm that linguistic similarity predicts a group's representation in the governing coalition even among non-coethnic groups.

In columns 4-6 I explore the allocation of top positions in the governing coalition, and in columns 7-9 the allocation of positions outside of the top.[38] In all cases the variables of interest are positive and statistically significant. The most notable observation in this table is remarkable consistency in the magnitude of non-coethnic similarity across specifications. Related groups outside of the leader's ethnic group benefit from receiving positions both low and high in the hierarchy of government.[39]

---

[38]Top positions include the president and deputies, as well as ministers of defence, budget, commerce, finance, treasury, economy, agriculture, justice, and state/foreign affairs.

[39]Though not reported here, the estimates for group size are statistically significant in all instances. The estimates are also comparable in magnitude to those in Table 3 of Francois et al. (2015), and similarity show evidence of concavity in the effect of group size.

This table reports benchmark estimates associating each measure of linguistic similarity with night light luminosity for the years $t = 1992 - 2013$. Average night light luminosity is measured in language group l of country c in year t, and linguistic similarity measures the similarity between each language group and the ethnolinguistic identity of country c's leader in year $t - 1$. Lexicostatistical similarity is a continuous measure of a language pair's phonological similarity and is measured on the unit interval. Cladistic similarity is a discrete measure of similarity representing a language pair's ratio of shared branches on the Ethnologue language tree. Coethnic is binary measure of linguistic similarity that takes a value of 1 when language group l is also the ethnolinguistic identity of country c's leader. Distance & population density measure the log distance between each country-language group and the leader's ethnolinguistic group, and the log population density of a country-language group, respectively. The geographic controls include the absolute difference in elevation, ruggedness, precipitation, temperature and the caloric suitability index between leader and country-language group regions, in addition to two dummy variables indicating if either region contains diamond and oil deposits. Standard errors are clustered at the country-language group level and are reported in parentheses. * p < 0.10, ** p < 0.05, *** p < 0.01.

This table reports estimates from a subsample that excludes all ambiguous leadership assignments. Because these problematic assignments introduce measurement error, excluding them from the analysis ensures that the results are not a consequence of measurement. Average night light intensity is measured in language group l of country c in year t, and Lexicostatistical similarity is a continuous measure of language group l's phonological similarity to the national leader and is measured on the unit interval. The same log transformation of the dependent variable is used for the lagged value of night lights, i.e., $\ln(0.01 + NightLights_{c,l,t-1})$. All control variables are described in Table 3. Standard errors are clustered at the country-language group level and are reported in parentheses. * p < 0.10, ** p < 0.05, *** p < 0.01.

Adjusted R^2	0.990	0.990	0.990	0.990	0.990	0.990	0.990	0.990	0.990
Observations	6,610	6,610	6,610	6,610	6,610	6,610	6,610	6,610	6,610

This table reports the benchmark estimates weighted by Ethnologue language group population. Average night light luminosity is measured in language group l of country c in year t, and linguistic similarity measures the similarity between each language group and the ethnolinguistic identity of country c's leader in year $t-1$. Lexicostatistical similarity is a continuous measure of a language pair's phonological similarity and is measured on the unit interval. Cladistic similarity is a discrete measure of similarity representing a language pair's ratio of shared branches on the Ethnologue language tree. Coethnic is binary measure of linguistic similarity that takes a value of 1 when language group l is also the ethnolinguistic identity of country c's leader. All control variables are described in Table 3. Standard errors are clustered at the country-language group level and are reported in parentheses. * p < 0.10, ** p < 0.05, *** p < 0.01.

Table D8: Robustness Check: Benchmark Regressions with Alternative Dependent Variables

	$\sqrt{\text{nightLights}_{c,l,t}}$			$\ln(\text{nightLights}_{c,l,t})$			$\text{nightLights}_{c,l,t}$

Observations	6,610	6,610	6,610	2,921	2,921	2,921	5,098	5,098	5,098

This table tests the robustness of the dependent variable using two alternative transformations: a square root of the raw night lights data ($\sqrt{\text{nightLights}_{c,l,t}}$) and the natural log of the raw night lights data without a constant term ($\ln(\text{nightLights}_{c,l,t})$). Columns (7)-(9) are estimated using a Poisson pseudo maximum likelihood estimator. Average night light luminosity is measured in language group l of country c in year t, and linguistic similarity measures the similarity between each language group and the ethnolinguistic identity of country c's leader in year $t-1$. Lexicostatistical similarity is a continuous measure of a language pair's phonological similarity and is measured on the unit interval. Cladistic similarity is a discrete measure of similarity representing a language pair's ratio of shared branches on the Ethnologue language tree. Coethnic is binary measure of linguistic similarity that takes a value of 1 when language group l is also the ethnolinguistic identity of country c's leader. All control variables are described in Table 3. Standard errors are clustered at the country-language group level and are reported in parentheses. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Table D9: Robustness Check: Benchmark Regressions in First Differences

	Dependent Variable: ΔnightLights$_{c,l,t}$					
	(1)	(2)	(3)	(4)	(5)	(6)

Adjusted R^2	0.330	0.329	0.330	0.329	0.330	0.329
Observations	6,255	6,255	6,255	6,255	6,255	6,255

This table reproduces benchmark estimates in first differences on the raw night lights data. Average night light luminosity is measured in language group l of country c in year t, and linguistic similarity measures the similarity between each language group and the ethnolinguistic identity of country c's leader in year $t-1$. Lexicostatistical similarity is a continuous measure of a language pair's phonological similarity and is measured on the unit interval. Cladistic similarity is a discrete measure of similarity representing a language pair's ratio of shared branches on the Ethnologue language tree. Coethnic is binary measure of linguistic similarity that takes a value of 1 when language group l is also the ethnolinguistic identity of country c's leader. All control variables are first differenced and described in Table 3. Standard errors are clustered at the country-language group level and are reported in parentheses. * p < 0.10, ** p < 0.05, *** p < 0.01.

Table D10: Individual-Level Regressions: Locational and Individual Similarity

	(1)	(2)	(3)	(4)	(5)
	Dependent Variable: DHS Wealth Index

Language groups	20	20	20	20	20
Observations	56,455	56,455	56,455	56,455	56,455

This table provides estimates for two channels: the effect of individual and locational similarity on the DHS wealth index. The unit of observation is an individual. The rural indicator is equal to 1 if a respondent lives in a rural location. The individual set of control variables include age, age squared, a gender indicator variable, an indicator for respondents living in the capital city, 5 education fixed effects and 7 religion fixed effects. Distance to the coast and border are in kilometers. Standard errors are in parentheses and adjusted for clustering at the country-language-wave level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Table D11: Individual-Level Regressions: Locational and Individual Similarity

		Dependent Variable: DHS Wealth Index			
	(1)	(2)	(3)	(4)	(5)

Observations	56,455	56,455	56,455	56,455	56,455

This table reports estimates that test for favoritism outside of coethnic language partitions. The unit of observation is an individual. The rural indicator is equal to 1 if a respondent lives in a rural location. The individual set of control variables include age, age squared, a gender indicator variable and an indicator for respondents living in the capital city. Distance to the coast and border are in kilometers. Standard errors are in parentheses and adjusted for clustering at the country-language-wave level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Table D12: Individual-Level Regressions: Baseline Covariates

Countries	15	15	15	15	15	15	15	15	15
Ethnic groups	187	187	187	187	187	187	187	187	187
Adjusted R^2	0.665	0.664	0.668	0.539	0.521	0.541	0.544	0.549	0.548
Observations	2,539	2,539	2,539	2,539	2,539	2,539	2,539	2,539	2,539

This table establishes that linguistic similarity predicts an ethnic group's share in the governing coalition of a country. The unit of observation is an ethnic group. The dependent variable in columns (1)-(3) is the share of cabinet positions of an ethnic group in the governing coalition, whereas in columns (4)-(6) and (7)-(9) the dependent variable measures the cabinet share of top positions and low positions. The group size controls include a time-invariant measure of an ethnic group's share of the national population and its polynomial. Standard errors are in parentheses and adjusted for clustering at the country level. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.
